I wish to dedicate this book to the enlightened mentors in the field of integrative and functional medicine with whom I have had the honour to interact: Doctors Jeff Bland, Jeanne Drisko, Sam Queen, Roger Newton, Sidney MacDonald-Baker, Douglas Hunt and Robert P Heaney. Through their gifts of knowledge, they have provided the foundation for the powerful impact nutrition is experiencing in influencing human health. This textbook is a tribute to their genius.

–Diana Noland

This textbook is dedicated to all the integrative practitioners who taught me how to care for patients as people, those practitioners who are living and those who have slipped away and especially my students who taught me to keep up and stay on my toes. But most of all, what is important for practitioners who are finding their way, "Listen with your heart".

–Jeanne A. Drisko

This book is dedicated to my family, friends and close colleagues who've provided unconditional love and support throughout this and all my work; it is for my teachers, professors and students who've been my patient and unwavering mentors. Finally, this is for my patients and clients who have taught me more than I imagined possible about what it means to be a healthcare provider.

–Leigh Wagner

Foreword

The incidence of almost every chronic disease has increased relentlessly in every age group for the past 50 years. Diabetes which was once rare (<0.7% of the population) is now projected to affect 35% of the people in their lifetime. For the first time in American history, life expectancy has gone down several years in a row. Healthcare costs (or, more accurately, disease treatment costs) are now 20% of the GDP, increasing inevitably and bankrupting the country. Why is the healthcare system—which obviously has several areas of great success—failing dramatically everywhere else?

Because the common causes of disease are not being addressed.

Conventional medicine has been incredibly effective in many areas, such as injuries, overwhelming infections, congenital malformations and some cancers. However, this model does not work for everyday health and disease prevention. Unfortunately, the burden of chronic disease has become so widespread and severe that most medical treatment is now primarily for symptom control and prevention of even worse sequelae. Very little of medicine as actually practiced today addresses the real reasons why people are suffering such a huge and progressively increasing disease burden.

What are those unaddressed causes? To quote an inspirational functional medicine expert Sid Baker, MD: "Most of medicine is quite simple, get into people what they uniquely need and get out what they uniquely do not need". In other words, nutrition and detoxification—*according to patient's unique biochemical needs*.

Nutritional deficiencies are rampant in the population and are getting worse. Not only is the general public choosing food with lower nutrient density but also hybridization and synthetic fertilizers have decreased the trace nutrient content of the food. Almost the entire population is deficient in at least one nutrient and over half has multiple nutritional deficiencies according to conventional standards. But even worse, the environment has become increasingly contaminated by toxic metals and chemicals that displace nutrients, poison enzymes, damage DNA, disrupt cellular communications, increase inflammation and dramatically increase oxidative stress in all systems of the body.

With the genomics revolution, we now know that there is a huge variation between nutritional needs and toxin susceptibility. For example, some people's single nucleotide polymorphisms (SNPs) result in the lower functioning of their vitamin D receptor sites and need ten times the recommended daily allowance (RDA) of vitamin D to maintain their bones. Another example is the huge 1000-fold variation in the activity of liver Phase I detoxifying enzyme CYP2D6. This enzyme detoxifies 25% of prescription drugs and a number of environmental toxins. Those with a poorly functioning version of this detoxification enzyme are not only much more likely to have an adverse drug reaction to the standard dose of a prescription but also more likely to suffer a number of diseases, such as Parkinson's disease, if they are exposed to neurotoxins. With over 2 million SNPs, there are a huge number of examples of SNP variants requiring specialized attention.

This is why *Integrative and Functional Medicine Nutrition Therapy: Principles and Practices* is such an important textbook. Every clinician who wants to care for their patients in a curative way must recognize and understand the clinical presentations of *functional* nutritional deficiencies and toxin overload. Relying on blood (or other tissue) levels of nutrients or environmental toxins is an ineffective diagnostic strategy for many reasons. For example, measuring blood levels of B-vitamins is very misleading. Using the conventional range standards, only a small percentage of the public is deficient. But measuring levels of toxic metabolites, such as homocysteine and methylmalonic acid, which build up when a person has a functional deficiency of B-vitamins, elevated levels indicate increased risk of tissue damage. This means increased risk for heart disease, Alzheimer's disease, osteoporosis and other chronic degenerative diseases.

We see the same pattern with environmental toxins. For example, the "safe" levels of most toxins are established according to population norms. But the "normal" population suffers a huge disease burden! And as mentioned above, using absolute levels of toxin misses the huge variation in detoxification function found in the general population. Some people can smoke their entire life without apparent problems while a non-smoking spouse

gets lung cancer. There are numerous examples of common chronic diseases being primarily caused by the combination of nutritional deficiencies and toxin load in the context of biochemical susceptibility. Drugs do not reverse deficient nutrients or help increase toxin excretion. In fact, almost all drugs are yet another load on the already overloaded detoxification systems.

The only effective clinical strategy is that which thoughtfully *integrates* multiple diverse interventions that not only address the actual causes of disease but also utilizes safe therapies that optimize each person's unique physiological function.

This is the premise and promise of IFMNT.

Joseph Pizzorno, ND
Co-Author, Textbook of Natural Medicine
Chair of Board, Institute for Functional Medicine
Seattle, WA, USA

Preface

Over the past 50–60 years, the world has seen an unparalleled and unprecedented growth in non-communicable (chronic) disease. Chronic disease has replaced acute infectious disease and trauma as the dominant influence on healthcare delivery. Our current healthcare model is no longer sustainable, i.e. the captain of the ship making a brilliant diagnosis and delivering the silver bullet cure or surgically repairing the problem. No silver bullet exists that satisfactorily addresses the chronic, complex disorders that currently clog our healthcare systems. The health of our nation and world has changed rapidly while healthcare delivery has remained stagnant. But change, it must!

This urgently needed change does not appear to be coming from within large healthcare systems. However, healthcare consumers, especially those with chronic and life-threatening disorders, are demanding a different delivery of care. As one patient with chronic disease relayed, her primary care physician told her that she had so many problems he wouldn't be in practice long enough to solve them all. This is a message devoid of hope and care. In this setting, "care" is a misnomer as it has been stripped from healthcare by the abbreviated allotted visit times, and with practitioners no longer allowed to interact with those entrusted to their charge and prevented from knowing their patients as people.

The unifying theme of this textbook is the understanding of the nutritional status of patients. Without a strong nutritional foundation, healing of chronic disease is impossible. Unlike conventional medical care that narrowly defines nutrition, dismisses its importance and marginalizes its delivery, we propose that nutrition become a fundamental part of healthcare providers' broad scope. Without this foundation, our ability to successfully deliver care is limited. You will find within these pages authors with all types of backgrounds who have found success using integrative and functional medicine nutrition therapies when faced with chronic health conditions.

We wrote this textbook to help practitioners, health system leaders and policy makers to understand that there is a different and novel approach to address complex chronic disorders. Human physiology has not changed. What has changed are those factors acting on human physiology in the form of poor nutrition, environmental toxicant exposures, fractured human interactions, infrequent physical movement, stress, poor sleep and other lifestyle problems.

As editors with a collective 65 years of practice in integrative and functional medicine nutrition therapies, we have witnessed (and practiced) a new healthcare delivery system that incorporates important advances of conventional medical care that, combined with the original roots of healthcare, returns the patient back to the centre of the process. Partnering with patients fosters better understanding of the chronic disorders that plague them. We have witnessed how teams of practitioners with diverse healthcare backgrounds work together to find solutions to our looming healthcare crisis.

Although our backgrounds are in integrative and functional medicine, the model we present transcends and defies all labels and simply should be called "good medicine". In this textbook, we provide principles to illuminate understanding of how healthcare can be delivered to get to the root of chronic disorders. After the principles are laid out, the practice of "good healthcare" is described in detail. The reader will see that there is again hope for finding satisfaction in healthcare careers when burnout rates are soaring.

Within, you will find the underlying principles and practices laid out that give you, the reader, an understanding of the science of integrative and functional medicine nutrition therapies with real-world examples. The authors were selected because of their notable experience in integrative and functional medical nutrition therapies. This textbook will augment your journey back to the heart and soul of the practice of good healthcare.

The 10-year journey to writing *Integrative and Functional Medicine Nutrition Therapy: Principles and Practices* was the brainchild of editor Diana Noland. Diana collaborated with colleagues Jeanne Drisko and Leigh Wagner to successfully launch a master-level certificate program in integrative nutrition at the University of Kansas Health System in conjunction with the Department of Dietetics and Nutrition and the University of Kansas Integrative Medicine. We crafted materials to be used in the education of dietetic students but also used the materials in training all practitioners and students under our guidance. Their care for patients has

thrived with this underpinning. The development of this textbook provides a roadmap for care.

The editors and authors of this textbook have written this book in the hope that the knowledge it provides will help to achieve the day when all medical healthcare practices appreciate and include nutrition and lifestyle assessment and intervention for each unique individual.

We are thankful that this journey was guided by Coco and Roger Newton, who shared our vision for Integrative and Functional Medicine Nutrition Therapy: Principles and Practices. We also acknowledge our families who, for the past 3 years, have stood by us, supported our efforts and nurtured us while we wrote and edited, even during nights, weekends and family vacations. Special thanks to our spouses, Steve Noland, Robert Drisko II and Rob Bauer, who gave us insights and advice along this journey.

Many thanks to our faithful and accomplished copy editors, Matt Erickson and Jeffrey Field, who polished every chapter over the 2-year project.

Thanks to Michael D. Sova, our Springer developmental editor, who conducted the conversion from a vision to a reality. He brought together the work of individual authors to a cohesive collection of contributions toward providing the science and the practical aspects of integrative and functional medical nutrition therapy. Michael guided us in the preparation for a finished product and became an integral member of our team.

And finally, we would like to thank our friend, Dr. Joe Pizzorno, for writing the Foreword of the textbook as he joins us to express his common vision of the importance of nutrition therapy in the quest to quell the epidemics of chronic diseases in the twenty-first century.

ED	Erectile dysfunction
EEI	Equilibrium Energy Intake
EFA	Essential Fatty Acids
eNCPT	Electronic Nutrition Care Process Terminology
eNOS	Endothelial nitric oxide synthase
EPA	Eicosapentaenoic acid
ET	Exercise training
FAD	Flavin Adenine Dinucleotide
FDA	US Food and Drug Administration
FeNO	Exhaled fractional nitric oxide
FEV	Forced expiratory volume
FIGLU	Formiminoglutamate
FIP	Familial interstitial pneumonia
FPF	Familial pulmonary fibrosis
FUT2	Fucosyltransferase 2
GBS	Guillain Barre syndrome
GERD	Gastroesophageal reflux disease
GFN	Geometric Framework for Nutrition
GGT	*Gamma-glutamyl transpeptidase*
GLA	Gamma-linolenic acid
GMP	Guanosine monophosphate
GPx	*Glutathione peroxidase*
GSH	Reduced glutathione
GSSG	Oxidized glutathione
GTP	Guanosine triphosphate
HAP	Hospital-acquired pneumonia
HDL	High-density lipoprotein
henceforth NPE	Non-protein energy
HFE	Hemochromatosis gene
$HGBA_1C$	Hemoglobin A_1c
HIIT	High-intensity interval training
HTN	Hypertension
HVA	Homovanillate
ICW	Intracellular water
IFMNT	Integrative and Functional Medical Nutrition Therapy
IFN	Integrative and functional nutrition
ILD	Interstitial lung disease

IP3	Inositol triphosphate
IPF	Idiopathic pulmonary fibrosis
IR	Insulin resistance
IRDS	Infant Respiratory Distress Syndrome
ISMET	Integrated standing, movement, and exercise training
LA	Linoleic acid
LC	Lung cancer
LDL	Low-density lipoprotein
LT	Leukotrienes
LTB	Leukotriene B_4 (LTB_4)
LTD	Leukotriene D_4 (LTD_4)
LTE	Leukotriene E_4 (LTE_4)
MAO-A	Monoamine Oxidase A
MAO-B	Monoamine oxidase-B
MCT	Medium-chain triglycerides
MetSyn	Metabolic syndrome
MMA	Methylmalonic acid
MNT	Medical nutrition therapy
MRI	Magnetic resonance imaging
MSQ	Medical symptoms questionnaire
MTHFR	Methylenetetrahydrofolate reductase
MTR	Methionine synthase
MTRR	Methionine synthase reductase
MUFA	Monounsaturated fatty acids
NAC	N-acetyl cysteine
NADPH, NADP+, iNOS	Inducible nitric oxide synthase
NAFLD	Nonalcoholic fatty liver disease
NASH	Nonalcoholic steatohepatitis
NCP	Nutrition Care Process
NIBLETS	Nutrition, inflammation, biochemical individuality, lifestyle, energy and metabolism, toxic load, and stress
NIH	National Institute of Health
nNOS	Nitric oxide synthase 1
NO	Nitric oxide
NOS	Nitric oxide synthase
NOS1	Nitric oxide synthase 1
NOS2	Nitric oxide synthase 2
NOS3	Nitric oxide synthase 3
NPE	Nutrition physical exam
NSAID	Nonsteroidal anti-inflammatory drugs
NSCLC	Non-small-cell lung cancer
P	Protein
P5P	Pyridoxal-5-phosphate
PA	Phase angle
PAH	Phenylalanine hydroxylase
PAH	Pulmonary arterial hypertension
PDE5	Phosphodiesterase type 5
PDXK	Pyridoxal kinase
PES statement	Problem-etiology-signs and symptoms
PG	Prostaglandins
PGE	Prostaglandin E_2
PGG	Prostaglandin G_2
PGH	Prostaglandin H_2
PLH	Protein leverage hypothesis
PN	Parenteral nutrition
PNMT	Phenylethenolamine N-methyltransferase
PUFA	Polyunsaturated fatty acids
RA	Rheumatoid arthritis
RBC	Red blood cell
RMT	Right-angled mixture triangle
SAH	S-Adenosylhomocysteine
SAM	S-Adenosylmethionine
SCFA	Short-chain fatty acids
SCLC	Small-cell lung cancer
SIT	Sprint intensity training
SMA	α-smooth muscle actin
SMART goal	Specific, measurable, accountable, reachable/realistic, and timely
SNP	Single-nucleotide polymorphism
SOD	Superoxide dismutase
sTFR	Soluble transferrin receptor
SUOX	Sulfite oxidase
TBW	Total body water
TETR	Therapeutic ET for Rehabilitation
TG	Triglycerides
TH	Tyrosine hydroxylase
THF	Tetrahydrofolate
TIBC	Total iron binding capacity
TPH	Tryptophan hydroxylase
TX	Thromboxanes
TXA	Thromboxane A
VAP	Ventilator-associated pneumonia
W_3	Omega-3
W_6	Omega-6
WHR	Waist-to-hip ratio

1.1 Introduction: The Problem

At an interim meeting of the American Medical Association in November 2018, AMA President Barbara McAneny, MD, called the current US health system "dysfunctional" [1]. As Dr. McAneny stated, "the current system is working to improve hospital and insurance-payer bottom lines, but not working as intended for patients or the doctors who care for them." She went on to describe how the system, with its ever-growing appetite for consolidating businesses and health systems, is getting in the way of actual healthcare. As insurance payers place egregious restrictions on healthcare providers, the health plan determines the course of care, regardless of the patient's needs or the provider's preferred interventions. Dr. McAneny stated, "We are witness to greater concentration of wealth and power in the hands of ever-larger corporations with more and more middlemen pulling down large salaries while our patients go broke and physician practices struggle to survive."

An example of a recent merger is the pharmacy giant, CVS, joining insurance company, Aetna [2]. CVS CEO Larry Merlo said he envisions "CVS Pharmacy evolving from not just a store that happens to have a pharmacy and products" into "more of a healthcare destination." Merlo added that CVS will continue to offer retail products, though its retail sales grew only 1.5% in the first 9 months of 2018. CVS already has MinuteClinic locations at many of its stores, but the company plans to branch out into other comprehensive, community-based healthcare services in the wake of the Aetna deal.

With more than 500 hospital mergers between 2010 and 2015, nearly half of the hospital markets in the United States are now highly concentrated, with many areas of the country dominated by one or two large health systems [3]. Large systems are less nimble and have difficulty responding to market shifts. As healthcare markets concentrate, CEOs focus more on growth than cost-cutting. In addition, hospital mergers have been leading to ever-increasing prices for healthcare consumers. Healthcare systems are also facing challenges to their business models because new types of healthcare venues will shake up the market. These new venues include retail clinics, outpatient urgent care centers, laboratory service-based providers in shopping centers, upcoming projects from tech giants like Amazon and Apple, telehealth services, and the potential for additional mergers between payers and retail pharmacies [3].

The insurance payer market is also consolidating, with many large metropolitan areas dominated by companies that make up at least 50% of the market share [3, 4]. As reimbursement rates to healthcare consumers decline, many now pay more out-of-pocket expenses and are willing to switch healthcare providers to get faster appointments, more convenient locations, better services, and greater cost transparency. This chaos will certainly tax the large conglomerates to provide models of healthcare delivery and payment that will further stress their infrastructure. Currently, the dominant payer system keeps healthcare providers dependent on its strategies instead of emphasizing quality and value.

Electronic health record (EHR) technology, another growing concern for medical practices, grew out of billing software and works for payers whether they are private or federal [1, 3]. The EHR industry remains fragmented across the United States with large vendors dominating but not controlling the market [1, 3]. A single EHR seems unlikely and, as a result, chronic care providers will continue to struggle to capture, share, and use data from the wide number of disparate EHR systems. Most current EHR system users aren't satisfied and many patients question who will have access to their personal data. We need technology that works for patient care, not proprietary software that blocks information gathering between different healthcare providers. The archaic paper documentation, data entry, and faxing must cease [1]. A RAND Corporation study of physician payment methods found an overemphasis on EHR data entry payment models rather than documentation of the healthcare provider-patient relationship that is essential for the success of patient care [5].

The gold standard for clinical decision-making, evidence-based medicine (EBM), has been called into question with its narrowly designed definition and increasing conflicts of interest. As early as 2005, concerns about falsification in published research were raised [6]. The author went on to claim there was proof that most research findings are false. Subsequently, Horton's 2015 Lancet editorial made a straightforward case against EBM in which he said, "much of the scientific literature, perhaps half, may simply be untrue" [7]. Specific concerns that included invalid exploratory analysis, flagrant conflicts of interest, and an obsession for pursuing fashionable trends in science of dubious importance led him to write, "[S]cience has taken a turn towards darkness." The editorial goes on to highlight the fact that research universities are in a struggle for money and talent and these and other reductive metrics incentivize bad practices. One of the most significant concerns about bias in EBM is financial conflicts of interest [8, 9]. As the growing cost of science and research has outstripped the ability of federal funding, industry and the private sector have stepped into the gap. Unfortunately, those in industry who give the research dollars and support the infrastructure also have a hand in research design, conduct, and publication of findings with significant concerns regarding bias. Financial conflicts of interest with ties to industry are placing undue influence on researchers. A recent prominent example is José Baselga, MD, who was forced to resign as chief medical officer of Memorial Sloan Kettering after it came to light that he failed to disclose millions of dollars in payments from pharmaceutical companies in dozens of published research articles [10]. Although Dr. Baselga claimed the oversight was inadvertent, *The New England Journal of Medicine* editors described his failure as a "breach of trust" [11]. This and other breaches of trust have confirmed that EBM has been hijacked, placing limitations on use of the published evidence that degrade the doctor-patient relationship and flagrantly disregard patient values [9]. As top researchers, federal funders, and most journals call for action, the bad news is no one seems ready to act.

The above changes and challenges have resulted in greater frustrations for practitioners in the trenches caring for patients, leading to burnout and increased suicides [1, 12, 13]. Healthcare providers feel a loss of control over delivery of care with more patient encounters shoehorned into the workday. For every patient they see, they spend two or three times as much time on EHR documentation, with approximately 25% of it spent outside of the clinic. Healthcare providers are not feeling good about the entire structure at the end of the day. It is this loss of autonomy and control over the practice of medicine that is leading to the crisis. And, as Dr. McAneny says, "Yoga at lunch won't fix this" [1].

Healthcare costs at the current growth rate are unsustainable at $3 trillion, and chronic noncommunicable disease accounts for the vast majority of every healthcare dollar expenditure [14–17]. It is time to reimagine medical education, chronic disease care, and EHR data liquidity and to eliminate dysfunctional healthcare. The traditional healthcare model focuses on acute care with a singular focus on hospital-centered care built around ever-expanding large health systems [4]. This current system seeks to continue the status quo and is attempting to improve the current processes within an unsustainable environment. To correct this destructive path, there is a call to change medical education with focus on chronic disease inside this current model. This will include short-term supplementation of the current conventional care system models with alternative care models. However, there are no processes in place or systems built in to help patients navigate and take charge of their healthcare and financial responsibilities. A futuristic view of medicine demands a consumer-centric healthcare delivery system, and the question remains if the current system can provide it [4].

The long-term goal for care delivery is change in the model and a predominant focus on preventive care [3, 4]. The patient will be a consumer of the healthcare system and will demand transparency in billing and access to medical information (see Fig. 1.1). This will require engaged medical personnel who are transparent and willing to embrace necessary change, especially in technology with interactive platforms and computer software that interfaces with medical records, physician offices, and all members of the health team. This will include integrated devices that transmit patient health data to providers. New ways to manage chronic disease effectively and efficiently while keeping patients at home will be required. Consumer input will be expected, making clear what they need and want from their healthcare providers. Guidance will come from leading consumer-centered practices from industries outside of healthcare. In the end, there will be transparency of pricing, quality data, and technology that engages patients, as well as personalized care delivery. When patients and their healthcare providers are engaged in this process, it will become a powerful disruptive force to the current model. The mandate is on healthcare systems to transform or become obsolete. It is important for change agents and disruptors to take risks, partner with innovators, be creative, and engage healthcare team members in the process.

Fig. 1.1 What patients want. (Reprinted with permission from iStockphoto LP)

Who will lead the charge for change? It will not be Big Pharma or healthcare insurance plans or health systems. It is the burden of medical professionals and consumers to become the agents for change and disruptors of this dysfunctional system. Healthcare providers need training to intervene early in the continuum of chronic disease and be able to teach patients to stay healthy, exercise, and choose nutritious foods. The healthcare workforce needs to become partners and educators of patients and speak up for patient equity and ethical treatment and demand that patients have a voice. We have been called to a mission to be dedicated medical professionals and, as such, willing to design a system that values health over money, power, and politics.

1.2 Brief History of Medicine

A brief history of medicine is in order to understand its evolution and how we have found ourselves at this crossroad. Medicine arose from a superstitious approach of ancient civilizations with the healer as a philosopher, physician, and priest [18]. This mindset continued until the Renaissance and blossoming of scientific approaches during the Enlightenment. Medicine likely developed out of the primal sympathy of man for fellow man and out of the desire to help those in sorrow, need, and sickness. This basis of compassionate medicine continues and is rooted in sympathy and the desire to help others.

For many millennia, priests and physicians were co-identified in the practice of medicine and medicine was never fully dissociated from religion. Because of evil spirits and angry gods, man needed emetics, purgatives, enemas, diuretics, and bleeding to rid these demons from the ailing body [18]. A rich pharmacopeia was available during this time as has been identified from recovered papyri. The community used animal body parts and secretions and other elements derived from nature such as opium, hemlock, copper, salts, and castor oil. Crude surgical procedures were employed with historical records of some of these interventions surviving to modern times.

Medicine passed from the rich Egyptian culture to the Assyrians and Babylonians with the ascendancy of these later cultures and the decline of Egypt. Medicine developed to a higher stage but continued to ascribe to evil spirits and demons as the cause of illness and use practices to predict the future. One practice was for physicians to examine animal organs, particularly the liver, which was believed to be an important seat of the soul, vitality, mind, and emotions. This led to anatomical models and the understanding and observation of anatomy. These were related to the priest/healer's yearning to peer into the minds of the gods.

Greek medical schools arose as early as the fifth century BCE where the appreciation between anatomy and physiology was recognized [18]. It was at this time that the doctrine of humors arose. Healers strove to keep equilibrium of the humors – blood, phlegm, yellow bile, and black bile – because health maintenance and disturbances were equated with disease. It was also during the time of the Greeks that shrines and temples arose where climate, diet, and hygiene became important in healing. These locations were often associated with mineral springs and incorporated exercise, baths, and the use of oils and ointments on the body. Prescribed diets, along with prayers and sacrifice, were administered. Libraries with records of treatments, therapies, operations, and all types of medicines were established with some of these records surviving to modern times.

Hippocrates is the father of modern medicine and he richly influenced the evolution of its science and art. He noted that the healer provides service to the community and must aim to be useful and make men better. Hippocrates directed the healer to correct lives and ethically conduct his own life. He must make the beautiful soul harmonize with the beautiful body, as it is the duty of the healer to respect and care for the body [18]. Hippocrates instructed healers to employ consultations when necessary and pushing for fees was discouraged. The healer was to choose the least sensational method and not pretend to be infallible. Above all, cleanliness was to be valued. Because of the high order of mandates established by Hippocrates, bylaws were instituted regulating the personal behavior of physicians. By setting aside the roots of mysticism, superstition, and religious ritual, Greeks began looking to nature and the science of man to base accurate observations. There is no mention of divination, incantations, or charms from the Greeks. They recognized that disease is part of nature, not divine or sacred, and the old beliefs were ascribed to ignorance.

The Greeks expanded the understanding of anatomy as it pertained to the heart, circulation, and pulmonary system, although accurate circulation was not described until much later. The Alexandrian school under the Ptolemies opened a university with the study of literature, science, arts, and medicine, and early understanding of the structure of the human body was defined by limited dissection. Physical exam, to include pulses and other observations, was developed to look for the cause of disease. Galen's program began teaching by example, visiting the ill at the bedside, and this method of ward rounds continues to this day.

Medieval medicine saw the light of learning burn low and flicker almost to extinction. The gifts of knowledge from Athens and Alexandria were deliberately cast aside after the barbarians invaded Rome and civilization was reduced to a wilderness [18]. During this time, Christianity wrought changes in the approach to medicine by reviling the body and all evil on earth. This had profound negative effects by stagnating the evolution of medicine. Science was disregarded as unnecessary. The light of scientific medicine from the ancients was almost lost in the morass of the Middle Ages, but was revived in the Renaissance. With the reintroduction of universities in the thirteenth century, guilds of students were attached to a famous teacher, and the study of anatomy was revived [18]. The rising of the sun of science dawned, and of many, one notable, Roger Bacon, advocated experimental science. Treatments were prescribed accordingly and some of these doctrines reach into modern days.

As the Greek writers of medicine were rediscovered in the fifteenth century, physicians became naturalists and botanists and interested in humanities. The sixteenth and seventeenth centuries saw the foundation laid for accurate knowledge of the structure and function of the human body and how it should be studied. Chemistry was elevated with many important discoveries advanced. It was during this time that Vesalius, a Belgian by birth but a teacher in Padua, began the study of anatomy through dissection of the human body with one of the greatest books of the world published with his anatomical dissections. However, Vesalius was reviled for his work because it was so revolutionary and unfavorable false reports about his character were spread widely [18].

William Harvey was trained by the Paduan Italian anatomists and returned to England, eventually teaching at the College of Physicians in 1604. He was the first to thoroughly describe structure and function of the organs of the thorax with accurate understanding of the workings of the heart and circulation of the blood. It has been stated what Vesalius did for anatomy, Harvey did for physiology [18]. Harvey had a special gift to prove experimentally what he hypothesized and developed the spirit of modern sciences. It was through luminaries like Harvey, Bacon, and Descartes that experimental research became the mode, with superstition and religion finally removed. The beginnings of modern medicine began in the 1680s by incorporating anatomy and physiology into education, and the use of postmortem dissection facilitated the association of illness with death. Systematic description and experiments ruled with truth overcoming dogma.

Herman Boerhaave's Dutch school was the epicenter of European medical learning in the early 1700s, with training in medicine, scientific method, and patient observations. Students were attracted to the Dutch school from all over the civilized world during this period. The Dutch method of instruction was brought back to Edinburgh by John Rutherford in 1747, augmenting the rise of the age of the Scottish Enlightenment. Rutherford taught at the Royal infirmary and was followed by William Cullen and Robert Whytt. It is important to note that Benjamin Rush, a young American physician and one of the signers of the Declaration of Independence, studied under Cullen in Edinburgh before returning to Philadelphia and establishing American medicine [19]. John Hunter organized pathological processes and determined that they were governed by laws of nature and subsequently accumulated, tabulated, and systematized this field of thought. Hunter reestablished the close union between medicine and the natural sciences and laid the foundation for collections and museums connected to medical schools. The systematic teaching of clinical medicine by ward rounds followed by amphitheater lectures became the standard mode of medical education.

By the end of the 1700s and through the 1800s, many great medical advances were made with only a few noted here. This included the birth of smallpox eradication by Edward Jenner through inoculation with cowpox. Jenner contributed to the beginning understanding of acquired immunity. Rene Laennec described the use of the stethoscope and began the practice of rigorous physical diagnosis. Richard Bright described renal disorders; Rudolph Virchow became the father of cellular pathology; Humphrey Davy described the use of nitrous oxide; and William Morton used ether, beginning the advent of surgical anesthesia. Louis Pasteur developed the understanding of plagues, fevers, and pestilence and described the epidemic spread of infection, which destroyed the spontaneous generation theory. Robert Koch showed the life cycle of infectious disease and developed Koch's postulate, while Joseph Lister developed the germ theory and destroyed the belief in miasmas or bad air causing disease. Great strides were taken at the close of the 1800s in the area of tuberculosis, malaria, sleeping sickness, and syphilis, and the ancient doctrine of Celsus was proved true: to determine the cause of the disease often leads to the remedy [18]. Thomas Addison, a physician at Guy's Hospital, described the adrenal glands and their function, which was followed closely by others with descriptions of the pancreas and its relation to diabetes, the thyroid, and the pituitary. Out of this grew chemistry and laboratory medicine with the foundation of the physiology and composition of expired air, blood, food components, excrement, urine, and metabolism.

With the understanding of the germ theory and attention to sanitation, preventive medicine was born. The attempts to fight poverty, filth, poor living conditions, and other public health measures helped stamp out typhus and reduce infections of malaria and yellow fever. Sanitation and improved living conditions reduced the burden of tuberculosis from about one million in the eighteenth century to half that number by 1911. The dawn of modern medicine through the first half of the twentieth century saw the reduction in acute illness or communicable disease and the ascendancy of chronic disease or noncommunicable disease that now plagues mankind worldwide [14].

The history of twentieth-century medicine would not be complete without discussion of the Flexner report. Published in 1910 after the Carnegie Foundation commissioned the study of US medical education [20], the project's overarching goal was to weed out medical schools that had no prerequisite educational requirements and no preparation in the basic sciences, those not associated with a university, and those with no systematic teaching of patient care by hospital rounds. Abraham Flexner felt his mission was to eliminate those who called themselves physicians but had received very little scientific education before or during medical school. Certainly, there was the need to elevate medical teaching and training with expansion of the medical sciences.

In Chapter X of the groundbreaking report, he detailed "illegitimate nonscientific" approaches that he called "Medical Sects" [20]. These groups included naturopaths or eclectic practitioners, herbalists, psychologists, homeopaths, chiropractors, and osteopaths, and these groups very quickly found their education and practice driven underground by the polemics of Flexner's disdain [20, 21]. The report also marginalized practices he felt to be unscientific, like social work and other disciplines like nutrition [20, 22].

1

Flexner advocated for the state board system that continues to license medical practitioners to this day [20, 23]. He noted that the state boards could reject applicants as an indirect method of discrediting the school which had given them their medical degree and, in his words, "[T]he board should summarily refuse to entertain the applicant's petition because his medical education rests upon no proper preliminary training. The full weight of its refusal would fall with crushing effect upon the school which sent him forth." In 1912, a group of the state licensing boards joined together to create the Federation of State Medical Boards [23]. This is neither a federal agency nor an independent governing body as the group voluntarily agreed to base its accreditation policies on academic standards determined by the American Medical Association's Council on Medical Education policies. Consequently, these decisions became the law of the medical land. A great deal of political power was placed in the hands of the American Medical Association that continued to suppress competing forms of medical practice well into the late twentieth century.

Although many excellent advances occurred because of improvements in the medical education system, there was a chilling effect of contracting medicine to reductionist strategies with established hierarchies. The job of medical care morphed in the early twentieth century after the development of drugs and advances in surgery. This led to drugs and surgery as the purview of physicians in dealing with acute care until the shift to chronic diseases made these approaches less successful. What suffered with the Flexner report was patient-centered humanistically oriented community medicine [21, 22]. Medical schools to this day continue to struggle to overcome the effects of standardization of American medical education [23]. All accredited American medical schools apply Flexner's "uniformly arduous and expensive" goals in medical education [23]. Unfortunately, with the rise in cost of chronic healthcare, many schools have been forced to make curricular changes and form corporate alliances because of the need to balance academic ideals with economic and social realities.

It is clear our current education and treatment systems are administered on the old foundations built during the era of acute communicable disease with heavy reliance on hospital rounds. But acute communicable disease has given way to dominance of chronic noncommunicable disease. Medical education must now include a curriculum that addresses the major cause of mortality and morbidity in the population that the health workforce serves and in the systems where they practice [22]. Will we be able to rebuild within the current system or find the need to construct a new model that will give home to the treatment of chronic noncommunicable disease? It is without question that medical education needs to undergo radical change and this poor foundation in education and treatment of chronic disease is largely to blame for the dysfunctional medical system, burnout of its caregivers, dissatisfied patients, and skyrocketing costs. Even Flexner believed that medical education must be accountable to the society that it serves [22]. Just as the Greeks and those physicians in the Renaissance and Enlightenment let go of the ancient ways while retaining the good parts, so should we let go of the acute care model that is collapsing and join forces with all types of practitioners to build a new model, with patient-centered humanistically oriented community medicine focusing on subduing chronic disease and supporting health-oriented citizens.

1.3 Changes Needed: Nutrition Education Across All Medical Education Systems, Interprofessional Teams, and New Systems of Care

1.3.1 Nutrition Education Across All Medical Education Systems: The Foundation

Worldwide, chronic disease will cause $17.3 trillion of accumulated economic losses over the next 20 years [16, 17]. These economic burdens are related to healthcare expenditures, reduced productivity, and lost capital and are the leading priorities of our time. The predominant risk factor for chronic disability and death worldwide is related to suboptimal diet and poor lifestyle choices [14, 24]. Diet-related coronary heart disease, stroke, type II diabetes, and obesity produce ever-growing global health burdens [14]. It is now evident that poor dietary habits contribute to obesity, low-density lipoprotein cholesterol increases, increased blood pressure, glucose-insulin irregularities, oxidative stress, inflammation, poor endothelial health, fatty liver, irregular adipocyte metabolism, abnormalities in hormone pathways of weight regulation, visceral adiposity, and destruction of the gut microbiome [17]. Unfortunately, the focus for decades has been a preoccupation on dietary recommendations that limit fat and cholesterol. It is now acknowledged the full health impact of fat-limited diets extend far beyond cholesterol pathways.

Dietary research and interventions evaluating overall metabolic risks have up to the present focused on single isolated nutrients rather than broad dietary patterns. Rather than isolated nutrients, a food-based approach better serves the general populations and minimizes industry manipulation [17]. Pushed by burgeoning obesity rates, nutrition research is beginning to focus on the quality and types of foods consumed that influence diverse pathways such as glucose-insulin response, hepatic lipogenesis, fat storage, and the microbiome. Armed with this new information, it is up to the healthcare team to work with individual patients and meet them in their sociocultural communities to create lasting changes in chronic disease burdens. However, new paradigms in nutrition are not being translated into clinical practice because of limits in medical education.

Medical education has a mandate to prepare students to face the types of clinical problems they will see in their everyday practices [25]. Medical education has predominantly occurred in a hospital setting with didactic lectures in amphitheaters and ward rounds consisting of education at a patient's bedside. There is a failure of medical education, and as a result the healthcare delivered, to adapt to transformations

that have occurred in the past 50 years, with chronic disease replacing acute disease as the dominant problem. While acute disease is episodic, commonly associated with hospitalization and a return to baseline health, chronic disease is constant with the prevailing belief there is rarely a cure. It can be argued that in order to find relief and possibly cures, chronic disease requires a change in delivery of care and its location with a broader emphasis on lifestyle and diet. Diet and nutrition are the foundation of health. Currently, medical education does not value nutrition education or understand its contributing role in chronic disease.

Poor nutrition as a leading cause of morbidity and mortality is competing with and perhaps outpacing the deleterious effects of tobacco and physical inactivity, but is largely unrecognized by conventional primary care providers related to limited nutrition education opportunities. As early as 1963, there were reports of deficiencies in nutrition education in conventional medical schools [26]. The authors acknowledged, "a close relationship between nutrition and the individual's response to pathologic stress, such as severe infections or trauma." They also acknowledged the relationship between nutrition and degenerative disease, atherosclerosis, hypertension, and neoplasia. At the time, there was a call to improve medical education and medical practice to keep "abreast of the tremendous advances in nutritional knowledge" [26]. Yet this call was not heeded.

Over the ensuing decades, the increasing burden of chronic, diet-related disease, including the obesity epidemic, was not matched with nutrition education in conventional medical education [27–29]. The neglect in teaching nutrition is a growing problem as the workforce is not armed with tools to address patients' lifestyle issues. The average amount of required nutrition education, at the time of one report, was noted to be 19.6 hours, while the number of schools offering a dedicated nutrition course fell 25% [28]. Rather than measuring hours of nutrition education and coursework, the focus should be on competencies. In fact, most medical education across disciplines does not even teach diet and nutrition beyond a few metabolic pathways. Barriers to the inclusion of nutrition in medical education include such factors as the focus on treating disease with drugs and surgery and the erroneous belief system that nutrition is insufficiently evidenced-based [28].

The research evidence base for nutrition is only in its infancy, having begun in earnest in the beginning of the twentieth century. It wasn't until the 1980s that US dietary guidelines focused on the nutritional basis of chronic disease [24, 27–29]. However, because of the historical emphasis in nutrition research on deficiency disease, the single-nutrient paradigm continued to dominate research approaches. As a result, the literature oversimplified the impact of dietary factors in chronic disease [17]. In addition, nutrition epidemiology is in need of "radical reform" [6]. As an example of the absurdity of focusing on the previous research paradigm, the author states " [E]ating 12 hazelnuts daily (1 oz) would prolong life by 12 years (i.e., one year per hazelnut), drinking 3 cups of coffee daily would achieve a similar gain of 12 extra years, and eating a single mandarin orange daily (80 g) would add 5 years of life. Conversely, consuming 1 egg daily would reduce life expectancy by 6 years, and eating 2 slices of bacon (30 g) daily would shorten life by a decade, an effect worse than smoking. Could these results possibly be true?" New paradigms of nutrition research are desperately needed.

As nutrition science research matures, there is agreement that diet, nutritional status, and lifestyle choices predispose or protect against many chronic diseases including heart disease, diabetes, and cardiovascular disease. Yet, uncertainty remains in evaluating dietary evidence for federal policy recommendations and broad public health statements. Unlike the pharmaceutical industry, where evidence-based medicine (EBM) evaluates drug effects and has done so for many years, this type of research and evidence has proved challenging when attempting to adapt it to nutrition and diet research. Notwithstanding the concerns regarding traditional EBM [6–9], researchers have not established clear guidelines to point the way to study the effects of nutrients in complex human systems combined with a lack of consensus on how to evaluate findings and establish policy and dietary guidelines.

It is imperative to remember that pharmaceutical drugs are often studied in a therapeutic intervention context, that is, to treat, cure, or mitigate disease. However, nutrients are studied with a focus on health promotion or disease risk reduction, again supporting the idea that there needs to be fundamentally different approaches in researching the two models. What is needed is evidence-based nutrition not built on principles of EBM or reliance on randomized controlled trials [30]. When comparing food and nutrients to pharmaceuticals, it is best to remember that drugs usually have single and targeted effects, are not homeostatically controlled by the body, and can be contrasted with true placebo. By way of comparison, nutrients work in complex systems, within an epigenetic framework, and in concert with other nutrients and simultaneously affect multiple cells, tissues, and organs because they are homeostatically controlled. An added consideration is how the research participant's baseline nutrient status will affect the response to nutrient intervention. Finally, in the EBM research model, single isolated nutrients are required to be evaluated; however, this approach could never be effective in the complex biochemical mammalian environment. Nutrients function in a vastly complex biochemical network subject to interplay of genetics, diet, lifestyle, activity, stress, and environmental toxins. Single-nutrient studies can never answer questions in this complex system, and their effects in long-latency chronic disease cannot be adequately assessed. Until a new paradigm is developed, it is likely that healthcare providers in the trenches caring for those with chronic disease will be reduced to technicians delivering evidence-based algorithms and guidelines. It is up to leaders in the field of nutrition to establish evidence-based nutrition research guidelines.

An example of this misguided research approach occurred in the 1980s and 1990s. Policymakers and healthcare practitioners believed saturated fats and cholesterol were the cause of coronary heart disease and obesity [17]. Over the past 30 years, the substitution of fats with simple carbohydrates

1

and sugar in processed food led to the rapid rise in the obesity epidemic and skyrocketing type II diabetes rates. Based on evidence, the 2015 Dietary Guidelines Advisory Committee concluded that low-fat diets had no effect on cardiovascular disease and recommended focus on healthful food-based dietary recommendations rich in healthful fats [31]. Fortunately, more sophisticated approaches are being discussed with a rapid transition away from the single-nutrient theories and surrogate outcomes.

We see a transition in a more modern understanding of diet in its relationship to chronic disease. The science of obesity in more educated circles is shifting away from simplistic ideas of energy balance and calorie counting with new research focused on the effects of food and diet patterns on complex physiologic pathways. Healthful food-based patterns of intake have been shown to be the most important for fighting obesity [31]. Poor dietary quality is associated with an increase in processed foods, resulting in loss of nutrients and fiber, including polyphenols, minerals, essential fatty acids, vitamins, and other bioactive food ingredients. Poor diet quality is a driver of excess dietary intake, which in turn influences metabolic risk and the increase in abdominal adiposity. Independent of calories, poor dietary quality strongly influences metabolic dysfunction and drives the increased risk of diabetes. With increases in processed carbohydrates and simple sugars, these diets contribute to insulin dysregulation and resistance over time [17].

Evidence shows that an educated patient achieves better outcomes and a collaborative medical environment further enhances this [32]. Patients need education in healthful dietary choices. Sadly, the public considers physicians to be one of the most trusted sources of nutrition-related information [25, 27–29]. Yet physicians and other healthcare providers lack core competencies to properly counsel and educate patients about nutrition and diet-related disease. Additional barriers beyond education in instituting these goals in the conventional medical encounter include shrinking medical encounter time and increased EHR burdens, leaving little room for discussion of diet and lifestyle interventions. There is a need for creativity and innovation for approaches in chronic disease intervention, beginning with medical education and extending into the care setting. Imaginative ways of interacting with patients besides a traditional physical encounter should be employed such as telemedicine, telephone, and email [4]. This model needs to be incorporated in conventional medical education across all disciplines, and these shared learning experiences need to be coupled with new understanding and new behaviors [25, 32]. This in no way conflicts with medical science or the care of acute disease in the hospital setting but rather allows the best of medical science and technology to care for all patients.

The Institute of Medicine report, *Crossing the Quality Chasm* [32] reported, "[T]he fundamental approach to medical education has not changed since 1910." There is now a call for medical care teams to be educated and to work together in a manner that shares management responsibilities and decisions for these new challenges. With this shared responsibility, patients with chronic disease will be better cared for. Educating patients and their families in self-management methods will make them a valuable member of this team as well.

Successful and sustainable improvements in patients with chronic disease can occur but will require close collaboration among multiple stakeholders, including interprofessional healthcare teams and the health systems they work in, policymakers, researchers, community organizations, schools, farmers, retailers, restaurants, and food manufacturers. In the clinic setting, evidence-based dietary interventions are needed for individual behavior changes. These approaches include goal-setting, in collaboration with the patient, that includes a personalized diet plan; self-monitoring that could be achieved with electronic diaries through web-based apps; regularly scheduled follow-ups with feedback on progress through telehealth, telephone, or electronic feedback; the use of interventions that include motivational interviewing; and consistent use of family and peer support. See Table 1.1 [17]. This will necessitate training interprofessional teams on

Table 1.1 Evidence-based approaches for individual behavior change in the clinic setting

Intervention	
1	*Specific, proximal, shared goals.* Set specific, proximal goals in collaboration with the patient, including a personalized plan to achieve the goals (e.g., increase fruits by 1 serving/day over the next 3 months)
2	*Self-monitoring.* Establish a strategy for self-monitoring, such as a dietary or physical activity diary or web-based or mobile phone application
3	*Scheduled follow-up.* Schedule regular follow-up (in-person, telephone, written, or electronic), with clear frequency and duration of contacts, to assess success, reinforce progress, and set new goals as necessary
4	*Regular feedback.* Provide feedback on progress toward goals, including using in-person, telephone, or electronic feedback
5	*Self-efficacy.* Increase the patient's perception that they can successfully change their behavior
6	*Motivational interviewing.* Use motivational interviewing when patients are resistant or ambivalent about behavior change
7	*Family and peer support.* Arrange long-term support from family, friends, or peers for behavior change, such as in workplace, school, or community programs
8	*Multicomponent approaches.* Combine two or more of the above strategies into the behavior change effort

Adapted from Mozaffarian [17]. With permission from Wolters Kluwer Health

evidence-based behavior change strategies and adopting new techniques such as telehealth and electronics systems to help assess, track, and report what specific dietary behaviors are occurring.

1.3.2 Interprofessional Teams: The Way Forward

Lifestyle and behavioral risks resulting in complex chronic disease along with shortages in the health workforce are taxing the medical system. It has been argued that even though the 1910 Flexner report sparked groundbreaking reforms in medical education, medical education has not kept pace with the current challenges that have produced ill-equipped graduates [33]. Because of the structure of medical education post-Flexner report, there was a tendency of various medical professionals to act in isolation from or even in competition with one another. There has been a call to redesign professional health education to capitalize on the interdependence of health professionals in this new age of complex chronic disease. The idea of a team of medical professionals joining forces to deliver patient-centered care for complex medical disorders in the community setting has been discussed for several decades [32, 34–38].

Chronic disease evolves over time with waxing and waning severity. Compared to acute disease in a hospital setting where the patient submits themselves to treatment, complex chronic disease demands involving the patient as an active partner in their care; and because of the complexity of chronic illness, it is essential that a coordinated team of healthcare providers unite in its management. The team provides continuity and organized integration of care that are essential elements and helps create a healing relationship with the patient. Because the patient is now an active partner, education of the patient as well as family members or other social support groups is paramount. It is important for the professional group of providers, the interprofessional team, to understand that their role has changed from the time when acute disease treatment was delivered to the patient to our current era of chronic disease where the patient is part of the decision-making team. The interprofessional team members are now professional guides and advisors, teaching the patient healthcare skills, and there is shared decision-making between the patient and the healthcare team demanding a treatment program tailored to the patient's specific needs and wishes. In addition, the location of treatment intervention changes from the hospital ward to the ambulatory setting, which can take on a variety of appearances and locations such as traditional outpatient clinics, health clubs, home settings, community centers, telemedicine, email, or group educational programs [4, 5, 39]. The location is of less importance than the partnership and relationship of the patient and the interprofessional team, which is central to the healing encounter.

In 2009, six organizations representing schools of health education came together to form the Interprofessional Education Collaborative (IPEC) with the goal of working together to promote and encourage interprofessional learning experiences [38]. This vision grew out of a desire to form an interprofessional collaborative practice to deliver safe, high-quality, accessible, patient-centered care. The intent was not to harmonize the educational experience but to build on each profession's expected competencies to enhance the interprofessional experience in patient care. To enable the vision to be fulfilled, it was acknowledged that students needed to interact with one another in a learning environment so that they would effectively become members of a clinical team. This was to help prepare future health professions for enhanced team-based care of patients and improve population health outcomes particularly with the growth of chronic disease. A report published in 2011 detailed the core competencies for interprofessional collaborative practice [38]. This report and its goal to change were widely accepted and adopted with dissemination of the competencies across multiple colleges of medical learning with increased incorporation as part of the required curriculum.

Between 2011 and 2016, the interprofessional collaborative team grew from 6 core members to 15, along with input from 60 other health professions [40], with expanded goals to create a shared taxonomy among all the health professions and to streamline and synergize educational activities, related assessments, and evaluation efforts. The updated 2016 report highlighted the Triple Aim, which includes improve the patient experience of care, improve the health of populations, and reduce the per capita cost of healthcare [40]. The group articulated shared ideals that translated to competencies and include professionalism and respect, using knowledge for the benefit of patients and populations, improving communication to promote and maintain health and prevent disease, and using teams to plan, deliver, and evaluate patient-centered care that is safe, timely, efficient, effective, and equitable [40]. But can the current conventional health system with shrinking office visit times and increasing EHR demands successfully deliver interprofessional team medicine?

It is the belief of this author and the authors of this textbook that an effective model of interprofessional teams has been in existence for several decades. An integrative and functional healthcare team has brought together a partnership of multiple types of providers with the focus on the patient [39, 41]. With the patient at the center, attention is on the roots of chronic disease with diet as the foundation, requiring a team of professionals with a wide variety of expertise. This type of practice is bringing enjoyment back into the practice of medicine. Integrative and functional medicine is using paradigms to address chronic disease, while conventional medicine remains stuck in its acute care model. As spiraling rates of burnout and suicides occur, conventional providers are finding their way into new models of practice, and as a result, the dominance of the acute care model will wane.

1

1.3.3 New Systems of Care: The Way Forward

In the Introduction, Fig 1.1 highlighted what patients want from their healthcare providers. Patients want to be part of the healthcare team with their preferences valued. Information sharing is the answer and educating patients is the key. The future of medicine depends on the partnership of the interprofessional team with patients while avoiding methods that limit patient access to self-care information. A startling example of the attempt to reduce patient self-care is seen in the recent report stating patients with type II diabetes are testing their blood sugar by glucometer more often than they need to [42]. Three medical societies, the American Academy of Family Physicians, the Society of General Internal Medicine, and the Endocrine Society, released a statement that type II diabetics do not benefit from tracking daily blood sugars. The information was collected from insurance data with a look at expense. This flies in the face of good medicine and reduces the partnership with patients. Patients are no longer to glean information from self-testing to learn what effects food and lifestyle factors have on blood sugar levels. As conventional frontline medical practitioners are no longer encouraged to partner with their patients, there has been the growth of other types of healthcare delivery that look at root cause with more effective models of intervention. An example of one of these models is the Virta Health system that was developed to intervene in type II diabetes with diet, lifestyle, and patient education [43]. When patients understand their disease and can discuss information with their healthcare providers, remarkable changes can occur even in such significant debilitating chronic illnesses as type II diabetes. Drugs and surgery are held in reserve and used only when necessary. These alternate models of healthcare delivery treat the root cause of chronic disease rather than immediately intervening with drugs and surgery, long the prevailing paradigm in conventional medicine.

As the Centers for Disease Control and Prevention (CDC) warns, obesity, cardiovascular disease, and diabetes are the leading causes of preventable mortality [24]; personalized lifestyle medicine is a growing paradigm that delivers a different approach to conventional acute care medicine. Personalized medicine is specifically tailored to the individual patient's lifestyle, environment, genetics, and preferences to develop strategies for improving health outcomes and managing chronic disease [44–46]. To address the crisis, personalized lifestyle medicine requires a new set of healthcare practitioner skills and competencies to address multiple risky behaviors and improve patient self-management. This can lead to designing patient-specific prescriptions for diet, exercise, stress reduction, and avoiding environmental toxicity by taking advantage of identification of genetic variants and functional laboratory biomarkers. This comprehensive personalized approach promises to promote the safety of conventional therapeutics while reducing the long-term cost of chronic disease care. Information gathered from this approach empowers patients to have more control over their health with partnership at the center in the therapeutic setting. However, a barrier to implementing this style of medicine is modest research underpinnings and tepid recommendations from policymakers.

Another barrier to instituting a patient-centered diet and lifestyle approach includes the challenge in dealing with the complexity and the often-insidious transition from health to chronic disease with late onset of symptoms. This requires a workforce willing and trained to reconsider reactionary treatments and interventions as first-line treatments and to shift toward diet and lifestyle interventions first, with an eye on long-term prevention. A framework for this type of medicine has been proposed and is labeled "P4" for predictive, preventive, personalized, and participatory [46]. The authors state this system was developed to move away from a reactive medical approach with expensive episodic acute care interventions delivered in conventional settings that results in minimal interactions between specialists and general practitioners, fragmented healthcare approaches with multiple prescription medications, scattered follow-up, and a suboptimal cost-effectiveness ratio of care delivered [46]. Chronic disease care under these new models can be preventive with drug and surgical interventions delayed until significantly later in life. This is proposed by adoption of a healthy lifestyle throughout the lifespan resulting in an extended healthspan with the duration of one's life spent in a state of wellness. The P4 framework also believes in reversing chronic disease once it has begun by lifestyle and dietary interventions, but must include the patient as a partner. It is also acknowledged that at some point in the continuum of chronic disease, it may be necessary to intervene with traditional healthcare with pharmacotherapy, surgery, and other interventions as management tools.

The P4 model and other models such as integrative medicine, naturopathy, functional medicine, nutritional medicine, and other systems capture this belief and put it into practice. Moving toward a modern, proactive healthcare system, different levels of intervention must be clearly defined, and the list of stakeholders invested in the implementation of this model must be expanded. Training programs have sprung up to fulfill the need for retooling the interprofessional workforce, but effective change demands an orchestrated language to help researchers, healthcare professionals, and stakeholders across a multitude of sectors to collaborate as efficiently as possible [44–46]. Businesses are being developed to help practitioners become financially successful in establishing these types of clinics but will certainly expand over the next decade [3, 4, 39].

A "Blueprint" for health system sustainability was recently released as a community-based model to help reduce the burden of preventable disease on the financially strapped National Health Service in the United Kingdom, but could also serve as a blueprint for the world as a whole [47]. The Blueprint identifies 12 domains of human health thrown out of balance by contemporary lifestyles (see Fig. 1.2) [47]. The most effective way of treating lifestyle disorders is with appropriate lifestyle changes that are tailored to individuals, their needs, and their circumstances. Such approaches,

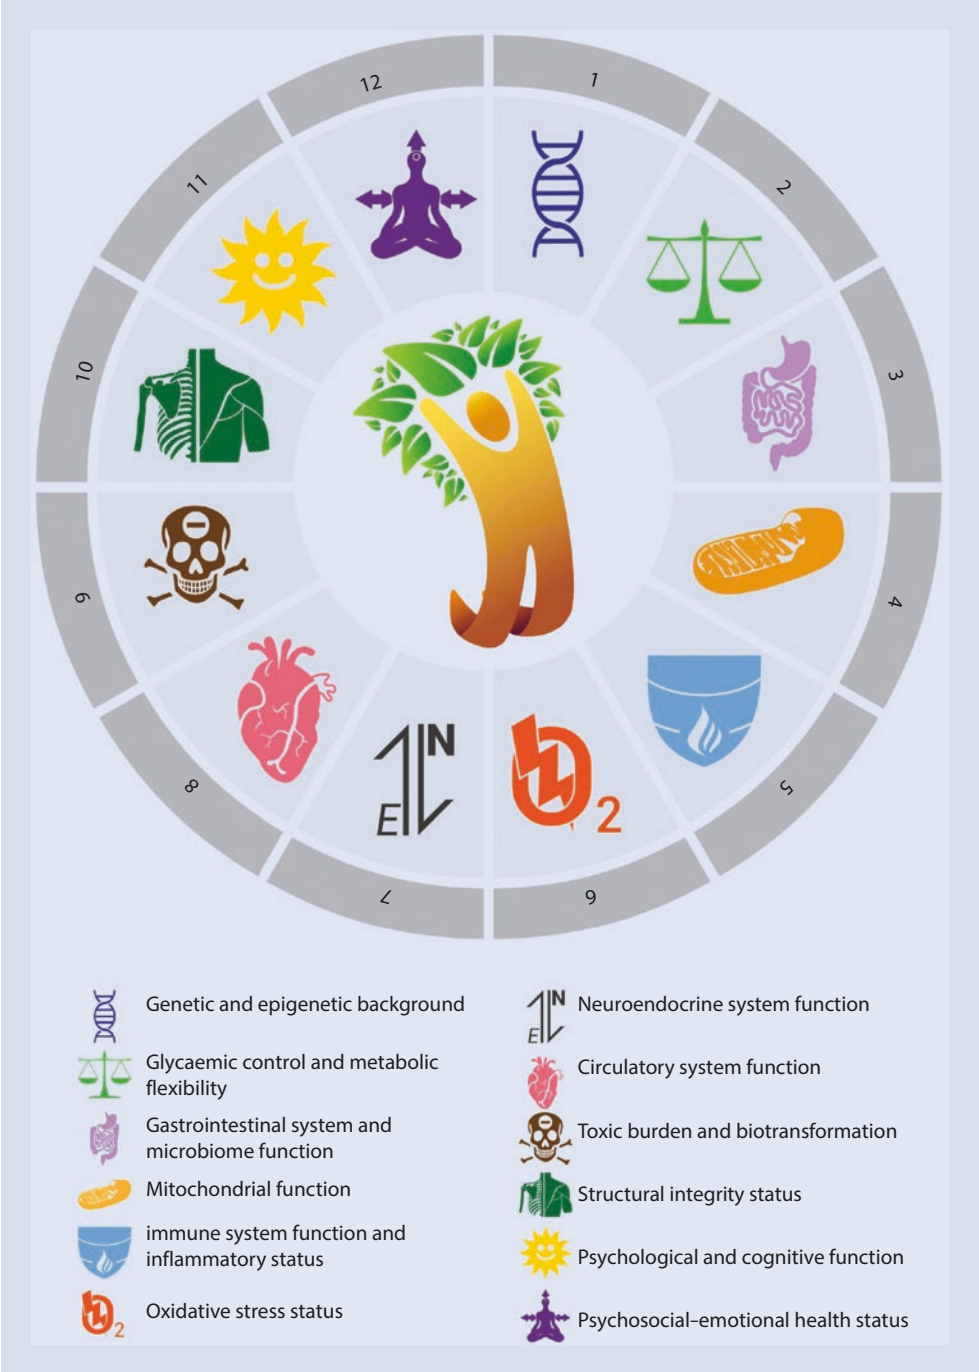

Fig. 1.2 The ecological terrain of an individual including 12 inter-connected domains of health and resilience

guided by the trained interprofessional team, tend to be far more economical and more sustainable as a means of maintaining or restoring people's health. At the core of a sustainable health system is one with individuals more responsible for maintaining their own health and where more effort is invested earlier in an individual's life prior to the manifestation of downstream chronic, degenerative, and preventable diseases. The report outlines hallmarks of sustainable health systems that are centered on the needs of individuals while also being focused on health creation or regeneration. Hallmarks include significantly reduced pharmaceutical use as first-line treatment for dietary and lifestyle-mediated disorders, financial and social frameworks that encourage the use of non-drug, lifestyle "prescriptions," and much greater engagement and autonomy by the individual.

The Blueprint acknowledges that implementing such seismic changes in the way healthcare is managed will be met with opposition [47], notably from those with interests in maintaining the status quo; however, identifying and addressing the barriers could transform some into opportunities. The most substantial and complex impediment will likely arise from the scientific community with the associated and limiting model of evidence-based medicine (EBM) as outlined above. New approaches to building evidence to guide

clinical decisions are being called for by federal agencies [48, 49]. It is imperative that we place the patient and practitioner back to the center of the decision-making process so that clinical choices can be based on evidence, personal experience of the doctor, and expectations of the patient [9]. Just as the promise of EBM has been the use of the best evidence, personalized precision medicine must also reintroduce the use of judgment. As one size does not fit all, it must be remembered that evidence-based medicine regards disease at the population level with minimal consideration of individuals. It is the call for personalized precision medicine approaches that need to be implemented allowing us to tailor interventions to our individual patients [9].

As patient-centered care in this current age requires a team, an effort to reconfigure and redesign health systems will require support from a team drawn from industry, politics, scientific and education communities, medical providers, and the consumers who ultimately will benefit. As the Blueprint [47] states, "To help develop a consensus approach that will allow progress towards more sustainable health systems…," transdisciplinary stakeholder working groups need to be formed that will develop assessment tools for outcome studies of health and resilience, economics of the proposed approaches, policy and regulatory measures, and approaches that minimize social inequality and maximize sustainability. It follows that the working groups will recommend pilot trials to establish proof of concept and the setting will include both clinical and nonclinical settings to evaluate effectiveness, value, and sustainability of the collaborative and participatory approaches. It is the belief of this author that subsequent larger-scale trials evaluating the proposed model of healthcare approaches will likely find reduced healthcare costs while improving health outcomes, value, and quality of life.

The final call is to forthrightly overcome biases and form consensus on what is required for the creation and management of necessary health systems. Well stated in the Blueprint [47], "We owe it to future generations to work urgently, earnestly and cooperatively together to develop and thoroughly evaluate new ways of managing and creating health in our society."

1.4 Conclusion

The time of crisis in healthcare is upon us, and difficult decisions need to be made to preserve good medicine for future generations. The acute care model in education and patient care will need to be moved aside to make room for solutions for chronic diseases that are swamping the system. Patients are demanding a place at the table to craft a way forward that engages them in the healing process. Disruptive elements in the technology world and in large corporations outside of medicine will make the current healthcare model obsolete. It will take brave actions and bold solutions. Will healthcare providers rise to the moment?

Seth Godin's Blog: Respect Difficult Problems [50]

» They're difficult because they resist simple solutions. Glib answers and over-simplification have been tried before, and failed.

» People have tried all of the obvious solutions. They haven't worked. That's why we've resorted to calling them difficult problems.

» Difficult problems require emotional labor, approaches that feel risky and methods that might not work. They reward patience, nuance and guts, and they will fight off brute force all day long.

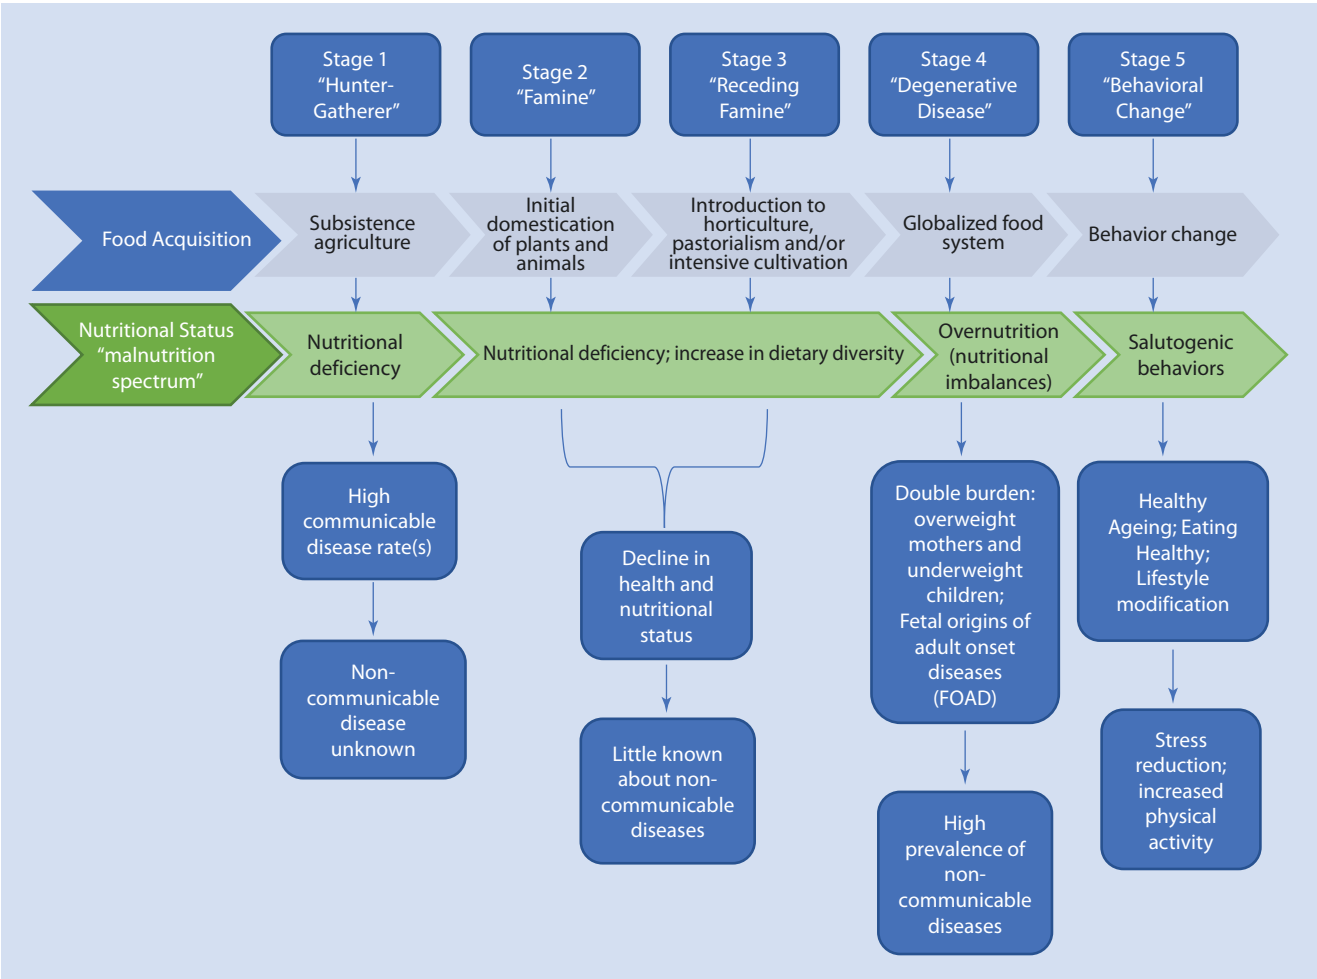
2.1 Nutrition Transition: A Model of Changing Dietary Patterns

Nutrition transition (NT) is a complex conceptual framework. It is rooted in the historic processes of demographic and epidemiological transition theories that describe trajectories in fertility, mortality, disease patterns, and causes of morbidity and mortality, respectively [1]. Nutrition transition is described by Barry Popkin as evolutionary stages or patterns (Fig. 2.1) that occur globally in a nonlinear fashion over time and space. Stage 1 is referred to as the "hunter-gatherer"; Stages 2 and 3 are termed "famine" and "receding famine"; Stages 4 and 5 are termed as "degenerative disease" and "behavioral change," respectively [please refer to Table 2.1] [2]. A majority of the writings on the subject draw attention to Stages 4 and 5, where dramatic shifts in diets, activity patterns, and health outcomes have been observed in different parts of the world over the last three centuries [3, 4]. Each stage is viewed as a pattern of food use and corresponding nutrition-related disease that affects individuals in the short term and populations in the long term [3]. In this view, each stage is a roadmap that highlights historical developments that occur in global societies during different time periods. Each stage is marked by specific patterns of food acquisition, food use, and physical activity with the ensuing stature, body composition, and nutrition-related health outcomes that affect individuals and, consequently, populations [5]. Transitory changes in food acquisition exist along a continuum, beginning with subsistence agriculture, progressing through industrialized agriculture to a globalized food system. Concomitant changes related to nutritional status lie along a spectrum of malnutrition ranging from undernutrition and nutritional deficiency to overnutrition

Table 2.1 Nutrition transition stages

Stage	Description
Stage 1	Hunter-gatherer
Stage 2	Famine
Stage 3	Receding famine
Stage 4	Degenerative disease
Stage 5	Behavioral change



Stage 1 "Hunter-Gatherer"
Stage 2 "Famine"
Stage 3 "Receding Famine"
Stage 4 "Degenerative Disease"
Stage 5 "Behavioral Change"
Food Acquisition
Subsistence agriculture
Initial domestication of plants and animals
Introduction to horticulture, pastorialism and/or intensive cultivation
Globalized food system
Behavior change
Nutritional Status "malnutrition spectrum"
Nutritional deficiency
Nutritional deficiency; increase in dietary diversity
Overnutrition (nutritional imbalances)
Salutogenic behaviors
High communicable disease rate(s)
Non-communicable disease unknown
Decline in health and nutritional status
Little known about non-communicable diseases
Double burden: overweight mothers and underweight children; Fetal origins of adult onset diseases (FOAD)
High prevalence of non-communicable diseases
Healthy Ageing; Eating Healthy; Lifestyle modification
Stress reduction; increased physical activity

Fig. 2.1 Stages of nutrition transition

and non-communicable diseases. The timing and degree to which these changes occur depends on the degree of development experienced by various global societies. Sociocultural and political factors, environmental conditions, degree of urbanization, industrialization, population demographics, migration dynamics, physical activity patterns, dietary acculturation, and the ability of the individual country's healthcare infrastructure to simultaneously handle infectious and chronic disease prevalence and incidence mediate these transitions and their health outcomes [6, 7].

2.2 The Changing Face of Food Over Time and Space

Stage 1 Stage 1 describes the myriad ways in which early global societies or "hunter-gatherers" engaged in food procurement and consumption practices. *Stages 2* and *3* mark the transition from a "hunting-gathering" society to a "food-producing" milieu. The latter was created with the advent of agriculture and the industrial revolution, along with the climatic and production fluctuations associated with these respective milestones. Regardless of location, dietary choices in *Stage 1* were limited to wild plant and animal foods indigenous to the geographic areas of inhabitance. For example, high-latitude populations such as the *Inuits* relied on seafood with almost no plant foods, while populations in the lower latitudes depended on fruits, nuts, roots, berries, and hunted or scavenged animal foods [8]. Stage 1 was noted for its (1) high degree of ecological availability, nutrient density, and need for dietary flexibility and (2) energy-intense food procurement activities. In general, humans experienced a shorter lifespan and non-communicable diseases were unknown [9]. However, at that time, there was a high probability of mortality from communicable diseases, inhospitable environmental conditions, and dangerous encounters [8].

Stage 2 The transition to *Stage 2* occurred with the initial domestication of plants and animals around 11,000 BCE, followed by the introduction of horticulture, pastoralism, and/or intensive cultivation.

Stage 3 In *Stage 3*, the domestication of plants and animals and the cultivation of one or more plant foods such as rice, wheat, or maize intensified. This shift is believed to have occurred in various locations around the globe at different times [8]. These activities provided populations with a plethora of locally harvested traditional or indigenous foods. Foods produced were native to the geographic area and not necessarily uniform across the globe; however, they were adequate in quantity and quality to meet the nutritional needs of the local population. For example, the *Inuits*' seafood-dominated diets were high in saturated fats with few carbohydrates, while the Balinese rice farmers [10], the Nigerian *Kofyars* [11], and the Papua New Guinea *Tsembaga* [12] relied on diets that were high in carbohydrates, including fiber, but low in fat, particularly saturated fats. Stability and abundance was ensured with the establishment and specialization of agriculture for the expanding populations. Cereals, legumes, and starchy foods became predominant dietary staples. Food was polysemic and served roles beyond sustenance. For instance, cultural anthropologists note that the first domesticated animals and plants were primarily bred and cultivated to be used as foods during feasts and for trading; they were symbols of power and status in addition to serving a hunger need [13]. Although the agriculture-oriented food system at that time ensured food security, it was limited in its resiliency to withstand shocks and vulnerabilities, such as droughts or floods that led to production swings and unpredictable availability [14]. *Stages 2 and 3* were marked by gradual decreases in diet diversity compared to *Stage 1*. Populations were subject to cycles of plenty and scarcity caused by migrations, political conflicts, overuse and degradation of natural resources, including soil fertility, arability, and unpredictable climatic conditions [8]. History is replete with instances of geographical regions subjected to such vulnerabilities resulting in famines, increased nutritional deficiencies, and a generalized weakened food supply with a growing dependence on foods from elsewhere [14]. Concomitantly, demographic changes marked by expanding populations and sociocultural and economic factors led to stratification by gender and social status, inequities, and unequal access to food and other basic necessities [15]. Historical records note the overall decline in health and nutritional status, citing maladies such as dental caries, anemia, and enamel defects, reduced stature and cortical bone thickness in various geographical locations [16, 17], yet through this period, little was known about the incidence and prevalence of non-communicable diseases.

2.3 The Globalization of Food

By the turn of the twentieth century, food procurement no longer remained an isolated activity that fostered self-reliance and kinship. Instead, the era's prevailing political, socioeconomic, and technological environments influenced food-related activities. For instance, the industrial revolution, rise of mechanization, new seed varieties, and the introduction of synthetic fertilizers caused massive shifts in the production, processing, distribution, and consumption of foods. The Green Revolution in South Asia in the 1960s and 1970s was credited as a success for its increased global yields; however, the following decades witnessed its consequences in the form of greater socioeconomic divides, poverty, catastrophic environmental degradation, and farmer suicides [18]. Parallel advancements in medicine; immunizations; antibiotics; sanitation and access to safe, good-quality water; the discovery of micronutrients; and, more recently, the expansion of healthcare technologies, e.g., telemedicine [19, 20], have since facilitated gradual improvements in the public's health.

Agriculture in the 1980s became a "global phenomenon" as its focus shifted from one of "traditional or indigenous foods" to a "cash crop" economy. Sugarcane, palm oil, wheat, soy, and animal source foods became agricultural trading commodities moving to the forefront to meet processing

demands [21]. At present, the scope of the food system has broadened from one of ensuring adequate food supplies to that of a financial enterprise governed by consolidation, economies of scale, money, and markets [22–24]. Selective breeding techniques, biotechnology, genetic engineering, fortification, enrichment strategies, expansion of the functional foods and nutraceutical categories, novel food processing and packaging technologies, and the introduction of information and communication technologies (ICTs) have facilitated increased yields of agricultural commodities, product innovation, diversification, and volume production of value-added processed and ultra-processed foods [25]. Precision agriculture or site-specific farming that combines global positioning systems (GPS) and geographic information systems (GIS) to monitor climatic conditions and provide farmers site-specific information is one such innovation in the agriculture realm [26, 27]. Farmers use this information to efficiently utilize and monitor their agricultural environments for crop planning, soil sampling, pest control, application, and yield mapping, mitigating several climatic fluctuations of previous centuries.

Advances in retailing, marketing, advertising, and the introduction of formalized markets provide a platform to inform and sell consumers the cornucopia of processed foods with different qualitative and nutritional attributes. Improved transportation, the development of domestic and international markets fueled by the expansion of global trade, and the introduction of high speed connectivity ensure better global food systems management while guaranteeing food access to large populations worldwide [27]. Continued urbanization, expanding populations consequent to global migration, and natural increases provide the necessary consumer base that sustains demand for these products. Further, the liberalization of trade policies is a key facet of the twenty-first-century globalization phenomenon facilitating trade across national borders. Low- and middle-income countries (LMICs), such as China, India, and Brazil, recognize the incentives and economic advantages of market-oriented agricultural policies [22] and have gradually liberalized their agricultural markets both domestically and internationally. Imports, exports, consolidation and merger activity in the food system, foreign direct investments (FDI), and the establishment of transnational food and beverage companies [28] have boosted economic developments in their food sectors [22]. Transnational entities such as Coca-Cola, PepsiCo, Nestle, Kraft, Carrefour, Danone, and Walmart have consequently expanded their markets and gained a significant foothold in emerging economies such as China, India, Brazil, and Mexico, thereby changing the scope and nature of these countries' food systems [29, 30].

2.3.1 Changing Trajectory of Populations' Lifestyles

The evolution of the globalized food system has proven to be a double-edged sword. Depending on the degree, pace of industrialization and globalization, different parts of the globe have experienced a mixed bag of positive and negative consequences and health outcomes [31, 32]. On the one hand, enormous economic developments and benefits to health and nutritional status have accrued in industrialized societies and the LMICs transitioning to *Stage 4* of the NT process [3]. Incomes have risen for many, poverty has declined, standards of living have improved, healthcare is more accessible, and these societies have seen a wider variety of processed foods, energy-saving devices, and technologies. Easy access to a globalized food system has fostered increased and varied consumption patterns worldwide, changing the trajectory of cultural foodways, value systems, human behaviors, and lifestyles of global populations [33, 34].

On the other hand, myriad challenges signaled by nutritional imbalances consequent to dietary pattern shifts, occupation-related stress, sharp divides in socioeconomic status, inequities in healthcare access, and chronic disease trajectories have risen for selected population segments such as the poor, women, and children [35]. A major consequence is the increased reliance on and dietary convergence of food components such as fats and oils, sugars, animal products, and processed and prepared products, all at the expense of traditional, indigenous foods [36]. High-, middle-, and low-income countries experience concomitant dietary pattern changes, such as increased portion sizes, eating out, and snacking frequency at varying rates [37, 38]. These patterns, coupled with a high degree of dietary convergence, are collectively referred to as the "Westernized diet or dietary patterns" [21, 36]. For instance, in the United States between 1977 and 2006, the overall energy intake from sweetened beverages increased by 135% while that from milk decreased by 38% [39, 40]. Sugar-sweetened beverages contributed a substantial amount of energy to the diet of Australian children, with mean intakes ranging from 4% in children 2–3 years of age to 7.5% in adolescents [41]. Mexico had the largest per capita (163 liters) intake of soft drinks in 2011 [42]. A market data analysis between 2000 and 2013 for ultra-processed food consumption by Euromonitor International for four lower-middle-income, three upper-middle-income, and five high-income Asian countries raised concerns about the growth in the carbonated soft drinks sector in the LMICs while their sales were declining or stagnating in high-income countries such as the United States [34]. Specifically, soft drink sales and volume were reported to be high in Thailand and in the Philippines, while sales of oils and fats were high in Malaysia.

Since the mid-1950s, developed countries have used specialized technologies such as oilseed breeding and oil extraction techniques to increase seed oil content, contributing to the widespread availability of cheap vegetable oils such as soybean, palm, and canola oils in LMICs of Asia and Latin America [43]. Between 1985 and 2010, vegetable oil consumption increased three- to sixfold in LMICs such as India and China. In India, the consumption of edible vegetable oils in urban and rural areas rose from 24 g/day to 36 g/day and 36 g/day to 48 g/day, respectively [44]. Data from China indicate that between 1994 and 2004, edible oil production increased nearly twofold in China, and 83% of the population had cook-

ing oil intakes over 28 g/day by 2010 [45]. Shifts in easy accessibility to vegetable oil [46], increasing market concentration in other food sectors, e.g., the beverage industry, coupled with growing fast food sales [21] have and continue to contribute to increased dietary fat intakes and global obesity rates.

2.3.2 Is the Nutrition Transition Experience Different Between the Developed and Developing World?

Despite varied and limited global epidemiological data on diet and physical activity, certain key differences exist between developed and developing countries. Developed countries, like the United States, carry a large burden of heart disease, cancer, diabetes, chronic pulmonary, and mental disease with a lower proportion of infectious diseases [47].

Stage 4 Since the 1980s, these countries have experienced *Stage 4* of the transition phenomenon with massive shifts in dietary and physical activity patterns resulting in body composition changes [32]. Adiposity, marked by a high BMI with the associated chronic inflammation and oxidative stress, is one of the well-documented risk factors at the nexus of the NCD concerns in this part of the world. Considerable scientific evidence reports that the high glycemic load, undesirable dietary fatty acid composition, altered macro- and micronutrient status, disturbed acid-base balance, unbalanced sodium and potassium ratios, and decreased dietary fiber content exacerbate the morbidities associated with NCDs [36].

Increasing dietary convergence to a more processed, westernized diet, a decline in traditional, indigenous food consumption, sedentary lifestyles, changes in average stature and body composition, and NCD morbidity and mortality are reflective of the LMICs transition phenomenon [21]. The complexity of these transitory changes and their contextual occurrence are noted by Corinna Hawkes as particularly pertinent to the nutrition-related non-communicable diseases or *Stage 4* in the nutrition transition spectrum. In a recent ecological analysis using multiple regression and cluster analysis on a sample of 98 countries across the globe, Oggioni et al. studied the association of obesity and diabetes with the agricultural, transitional, and Westernized dietary patterns. The Westernized dietary pattern had a direct dose-response association with diabetes prevalence, while the agricultural diet had the lowest prevalence of obesity and diabetes association [48]. Yet the NT experience of the LMICs is different and unique for several reasons.

First, the NT and disease pattern shifts in the LMICs of Asia, Africa, the Middle East, Latin America, and Oceania are occurring at an accelerated pace. Compared to the nearly five decades of transitory changes in the industrialized world, the LMIC transition has occurred over the last two decades. Further, the simultaneous population expansion consequent to a demographic transition from a high fertility and mortality pattern to one of low fertility and mortality has exacerbated the situation [49].

Second, according to Popkin [31, 32], there is considerable intra- and inter-country heterogeneity in transition patterns and health outcomes within and between different population segments. Ecological, internationalization, political, technological, and socioeconomic climates that prevail in the individual countries and/or regions during the transition phases are responsible for this heterogeneity. For instance, within Asia, China experienced great shifts in dietary and physical activity patterns between 1985 and 2000, while India's transition is still in the early stages and gaining momentum in urban areas [50, 51]. While the Chinese experience a high burden of hypertension followed by diabetes and cardiovascular disease, diabetes rates and susceptibility to cardiovascular disease in the South Asian region have skyrocketed in the last decade. India ranks highest in the world for diabetes incidence; Bangladesh accounts for 40% of all diabetes among the least developed countries and 10% of Pakistanis suffer from diabetes [52–54].

Third, obesity rates in many LMICs are two to five times greater than those of the industrialized countries with stark changes in specific subsets of the population – the poor, women, and children [55]. The UNICEF–World Bank–WHO group reports that the overweight prevalence in children is on the rise; between 1990 and 2014, the numbers have risen from 31 million to 41 million [56]. Since 2000, obesity rates for children under 5 years of age have risen by more than 50% in Africa and 40% in Asia [57]. Myriad reasons are fueling the obesity pandemic across the lifespan, increasing vulnerability and impacting health outcomes. These include unhealthy food choices, energy imbalances caused by sedentarism, chronic stress, and genetic and ethnic body composition predispositions that favors adiposity [58, 59]. Further exposure to environmental toxins, inequities in income and healthcare, healthcare systems that are unable to simultaneously handle chronic diseases caused by under- and overnutrition, and epigenetic fetal programming changes only make the situation worse [59].

2.3.3 A Growing Double Burden of Disease

The rising prevalence of obesity promotes a misconception that communicable and nutritional deficiency diseases are eradicated and supplanted by obesity and NCDs. However, this is far from reality [60]. Instead, global epidemiological data reflect the concurrent existence of undernutrition and overnutrition referred to as *the double burden of disease*. Compared to the developed world, the LMICs experience disproportionately large problems given the rapid globalization, economic growth, and population expansion these countries face [61, 62]. LMICs have always experienced a high incidence and prevalence of undernutrition, infectious and deficiency diseases driven by socioeconomic challenges, poverty, food insecurity, famine, and poor healthcare quality, access, and utilization. However, with nutrition and epidemiological transitions, LMICs face the additional challenge of a rapid increase in obesity and overweight sta-

tus. Accompanied by pathophysiological metabolic risk mediators such as hs-CRP, IL-6, obesity increases vulnerability to NCDs across the lifespan [63]. According to the annual WHO report, nearly 40 million people succumb to NCDs, accounting for 70% of all global deaths. Approximately 17 million die before age 70 and 87% of these premature deaths occurred in LMICs [64]. The metabolic syndrome, in which abdominal obesity and insulin resistance play a central role, is associated with a doubling of cardiovascular disease risk [65].

In a recent pooled analysis of 1698 population-based studies consisting of over 19 million male and female participants in over 180 countries, the prevalence of overweight and underweight using body mass indexes (BMIs) was studied over the 1975–2014 period. BMIs increased from 21.3 (1975) to 24.2 (2014) in men and from 21.7 to 24.6 in women, respectively [66], with some regions experiencing more accelerated rates than others. For instance, regional BMIs were highest for men (21.4–29.2) and (21.8–32.8) women in South Asia and the Polynesian islands, respectively. The prevalence of being underweight globally decreased from 13.8% to 8.8% in men and 14.6% to 9.7% in women; however, South Asia had the highest prevalence of underweight individuals at 23.4% and 24% in men and women, respectively. In 2014, of the 667 million children under five in the world, 159 million were stunted and 50 million were wasted [56].

Short-term consequences of the double burden of disease include malnutrition-related stunting and premature child deaths and compromised immunity, physical development, and cognitive abilities; long-term consequences include obesity, NCD-associated morbidities, and mortality. Ultimately this results in a lower productivity and quality of life in adulthood and higher healthcare costs [67]. The impact of these changes is variable between urban and rural populations, escalating with increased migration and changing food environments. The healthcare systems in LMICs lack the capacity and governance to address the double burden efficiently and adequately and the costs of treating NCDs are rising, consuming larger proportions of health budgets in LMICs. Initiatives such as the Millennium Development Goals, which were originally designed to combat undernutrition, are underway and need to keep pace with the NCD trajectory [68].

2.3.4 The Overlap Between Undernutrition and Overnutrition

The causes and consequences of both undernutrition and overnutrition as distinct health status entities are well described [48]; however, recent WHO reports and research from Africa, Mexico, the Middle East, and South Asia [69] highlight overlap of these two conditions, sometimes within the same household or individual. While the poor and uneducated are disproportionately affected, of particular concern are the long-term consequences in women at the population level [70–72]. At the individual level, the common manifestation of the double burden is the dual occurrence of energy imbalance and micronutrient deficiency. For example, between 1990 and 2005, obesity rates in West Africa increased by 114%, with more women affected than men [73]. In urban Burkina Faso, 73 out of 310 apparently healthy adults had one marker of overnutrition concurrently with at least one nutritional deficiency [61]. Studies using nationally representative data from three developing countries, Mexico, Peru, and Egypt, showed that overweight women were deficient in iron and other micronutrients such as vitamin A [74]. Reports from Sub-Saharan Africa note that while obesity is more prevalent among the affluent, more than 20% of women have BMIs of less than 18.5, 57.1% are anemic, and 18.5% are deficient in vitamin A [75, 76]. At the household level, the most common occurrence is a stunted child coexisting with an overweight mother [77]. The WHO classifies a country as experiencing a double burden of disease when at least 30% of children under 5 years old are stunted with an age-adjusted overweight rate for females above 25% [69].

Researchers interested in the fetal origins of adult-onset disease view undernutrition and overnutrition as being linked at the level of developmental programming and metabolic adaptation in the fetus, with important health consequences as individuals age and their environments change [78, 79]. In this regard, the double burden of disease in LMICs poses a threat both as a metabolic programming consequence of maternal undernutrition and a cause for NCDs in adult life. Epidemiologists attribute the NCD incidence in LMICs to perinatal and postnatal influences and reduced birth weight [80–82]. While public health focus continues to center on the mitigation of undernutrition [83], there is consensus that undernutrition, obesity, and NCDs are linked through the processes of developmental programming and metabolic adaptation that require immediate attention and action [84].

2.3.5 Metabolic Programming and NCDs

Developmental programming and metabolic adaptation are the major principles underlying the fetal origins of adult-onset diseases (FOAD) hypothesis, also known as the developmental origins of adult disease proposed by Barker in 1986 [85]. According to Barker, "adverse influences early in development and particularly during intrauterine life can result in permanent changes in physiology and metabolism, leading to an increased disease risk in adulthood" [86]. Prenatal insults include acute and chronic nutritional deficiencies, environmental influences such as smoking, exposure to endocrine disruptors, limitations in maternal physical stature, exposure to steroid hormone excesses, and maternal physiological and psychosomatic stress marked by elevated glucocorticoid hormones. These adverse influences pose several constraints during critical periods of fetal development, consequently altering tissue and organ development, structure and function which are also referred to as developmental programming [75, 87]. For instance, lowered intra-uterine protein

availability can modify pancreatic islet cell proliferation, causing future alterations in glucose homeostasis [88]. Undesirable fetal developmental programming in a compromised nutritional environment results in dysfunctional metabolic capacity and physiological function as future consequences. For instance, in utero stresses alter mitochondrial activity that influence the function of oxidative phosphorylation linked to skeletal muscle insulin resistance in type 2 diabetics [89]. The ensuing metabolic maladaptations in early life owing to inadequate maternal nutrition reflect the development of a thrifty phenotype with an altered metabolism that is beneficial to the survival of the fetus and anticipatory of a similar future postnatal environment. However, a mismatch occurs when there is a discrepancy in this expectation upon exposure to a food and a nutrient-rich environment, resulting in a greater susceptibility eventually culminating in obesity and metabolic disease [90]. While epidemiological and animal studies have garnered a large body of evidence, the mechanisms are yet to be elucidated. Suggested mechanisms include permanent alterations in cell numbers affecting structure and function of organs, inheritable epigenetic changes that affect DNA methylation patterns consequent to an altered maternal nutrient supply. These alterations potentially mediate the metabolic priming process very subtly through gene expression modulations [87, 91].

2.4 Pathophysiological Consequences of NT

Just as the germ theory provided a monocausal focus for infectious and communicable diseases [92], modern lifestyles are proposed as a major contributor to the NCD pandemic. Egger and Dixon [93], in a recent review on chronic disease determinants, describe the role of "anthropogens" in the etiology of meta-inflammation [94]. Anthropogens are man-made environments, their by-products and/or lifestyles encouraged by these, some of which may be detrimental to health [93]. Meta-inflammation is a low-grade, chronic systemic inflammation linked to a dysfunctional immune response. It differs from the classic, acute inflammatory response to infection and injury initiated by the body's innate immune system [95] in the following ways: first, chronic inflammation is low grade with systemic effects causing small rises in immune system markers such as proinflammatory cytokines, e.g., TNF alpha, hs-CRP, and interleukin 6; second, it is persistent, resulting in a chronic activation of the immune and neuroendocrine systems in an effort to bring about homeostasis; and third, it perpetuates a chronic, dysmetabolic state induced by anthropogens [93]. Although obesity is thought of as a prerequisite [96, 97], several behaviors linked to post-industrial, globalized lifestyles, e.g., poor diets, inactivity, stress, inadequate sleep, occupation, prescription and non-prescription drugs, smoking, toxic exposures, dysfunctional relationships, the social factors that encourage such lifestyle patterns over time, and the obesogenic environments in which they occur, e.g., technology, environment, occupation, air pollution [98], and endocrine-disrupting chemicals [99] are also pro-inflammatory. Viewed in the broader social, economic, and environmental contexts, anthropogens are extremely detrimental to human health. Anthropogens foster a chronic stress milieu, promoting a low-level, sustained chronic inflammation response. The innate immune system and the central stress axes are constantly activated without opportunity for the resolution and termination of the natural inflammatory response as seen in the acute stress response [95]. The proinflammatory cytokines either cause or are caused by dysmetabolic responses, leading to core imbalances in one or more of the body's physiological systems [100]. For example, unhealthy, calorie-dense, highly processed diets increase NCD risk, while feasting, cultural foodways, and changing food habits can act as moderators to enhance or decrease risk; chronic stress determined by an individual's coping capacity leads to elevated adrenocortical hormones and activation of the hypothalamic–pituitary–adrenal axis resulting in a host of vascular, metabolic, and inflammatory processes; obesogenic endocrine-disrupting chemicals (EDCs) and persistent organic pollutants (POPs) are documented to cause significant physiological and behavioral changes, e.g., increased appetite, ultimately contributing to obesity. Individual responses to the anthropogens are not uniform and dictated by genetic and epigenetic predispositions, as well as fetal programming [93, 101].

2.5 Anthropogens and Chronic Inflammation

Inflammation is the body's natural response to damage after injury or pathogen invasion. It is a self-limiting process consisting of an initiation, a resolution, and a termination phase. Its action is controlled by the synergistic roles of the innate immune system, the sympathetic nervous system, and the hypothalamus pituitary adrenal axis [95, 102]. The stress axes are involved in the response primarily through the action of norepinephrine and cortisol by modulating insulin and cortisol sensitivity. The efficiency of the response depends on the capability of the glucocorticoid and catecholamine receptors of the innate immune system. The inflammatory response is initiated by polymorphonuclear neutrophils that generate proinflammatory cytokines like leukotriene B4 and prostaglandins from arachidonic acid with the help of lipoxygenase 5 and cyclooxygenase 2 enzymes. While the leukotrienes exert their strong chemo-toxic response to the invading pathogen or stimulus, the prostaglandins regulate the switch to the second or resolution phase when their concentration equals that of the leukotrienes primarily by limiting the lipoxygenase enzyme activity. This phase is marked by high anti-inflammatory activity as seen in the production of specialized pro-resolving mediators (SPMs) such as *lipoxins*, *resolvins*, *protectins*, *and maresins* from eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) [103, 104]. SPMs are described recently to be involved in myriad mechanisms that promote the resolution and termination of the inflammatory response, such as switching off the stress axes,

enhancing microbial clearance through generation of non-cytotoxic macrophages. Both omega-6 and omega-3 fatty acids play critical roles in their biosynthesis and are expected to be of potential therapeutic value in microbial defense, pain, organ protection and tissue regeneration, wound healing, cancer, reproduction, and cognition [105–107].

2.5.1 Behavior Change for Positive Vitality

Stage 5 A growing awareness of the negative consequences of NCDs and/or the diagnosis of a chronic disorder such as diabetes prompts motivated individuals and communities to try and adopt a healthy lifestyle through behavior modification strategies. Stage 5, referred to as the behavior change stage, encompasses the various initiatives at the individual and population level that prevent or delay degenerative diseases and prolong life through healthy aging. It includes the practice of salutogenic behaviors that promote robust lifestyles, such as eating healthy foods, stress reduction, and increased physical activity. Healthy aging is "the condition of being alive, while having a highly preserved functioning of the metabolic, hormonal and neuroendocrine control systems at the organ, tissue and molecular levels" [108, 109]. Maintaining functional organ reserves and biological resiliency or the ability to adapt and/or withstand environmental stressors are at the core of the healthy aging concept. Furthermore, it is well recognized that healthy aging can be successful, provided a holistic multidimensional approach that addresses environmental, physiological, and psychological factors and healthy lifestyles is taken. For instance, a multifactorial behavior modification approach that includes programmed exercise activities, stress-reduction techniques like yoga and meditation, eating healthy foods like fruits and vegetables, and purchasing organic foods due to environmental concerns [110] can independently and synergistically contribute toward building and sustaining biological resiliency over the course of a lifetime. Personalized lifestyle medicine is one such approach that builds on the healthy aging concept using a combination of functional medicine principles [111] and innovative emerging *omic* technologies such as genomics, epigenetics, and diagnostic assessment tools [100]. Identifying the root cause of the disease rather than a symptom resolution approach, assessing for antecedents, triggers, and mediators, and keeping the biological uniqueness of the individual in perspective are major principles of functional medicine [112, 113]. Specialized assessment techniques such as nutrition-focused physical assessments and other functional diagnostic assessments, such as organic acid testing for assessing mitochondrial health and stool tests for gut permeability, are then employed to analyze an individual's NCD health metrics. Genomic analysis and testing [114, 115], molecular diagnostics, and tailored biomarkers are examples of specialized functional diagnostic techniques that provide personalized assessments and advice so that treatments can be individualized. They have the potential to improve health outcomes by developing sustainable lifestyle medicine-oriented strategies, empowering individuals so that they can be in control of their health [116–118] as well as facilitate the identification of clinical imbalances at an earlier stage before they become pathological.

2.5.2 Initiatives Addressing the Nutrition Transition

Nutrition transition underscores the need for all nations to build healthcare capacity and infrastructure, regardless of their economic status, to address the dual burden of malnutrition. This requires immediate action which necessitates healthcare and nutrition policies in developing countries to offer a more comprehensive integrated approach to address both undernutrition and overnutrition simultaneously. In a recent review of nutrition policies of 36 low-income, 48 low- and middle-income, and 55 upper-middle-income countries, only 39.6% had nutrition policies that addressed the dual burden of disease, while a majority of the countries' nutrition policies continue to focus on the mitigation of undernutrition [119]. The study further pointed out that having a nutrition policy in place did not necessarily translate into positive health outcomes. This highlights two important issues.

The first is the importance of a strong governance to facilitate the translation of the nation's policies into sustainable action and initiatives that are context-specific to individual countries [119]. Strong governance entails (1) stewardship; (2) development of surveillance systems that facilitate early detection of NCDs; (3) collaborative partnerships between stakeholders such as government, industry, health sector, consumers, and policymakers; (4) learning from previous experiences in other countries; and (5) strengthening the evidence base to enhance and support the design and implementation of health-promoting interventions [120–123].

The second is the need to focus policies that take on a life course approach to a healthy diet and physical activity lifestyle using culturally appropriate methods and messages initiated early in life [124]. This is the focus of the World Cancer Research Fund International's ongoing NOURISHING framework [125] for obesity prevention in 11 high-, middle-, and low-income countries (Fig. 2.2). The policy recommendations span across three critical factors that impact healthy eating and physical activity: food environment, food system, behavior change, and communication. This framework informs governments in these countries regarding appropriate interventions, such as restricting marketing of unhealthy foods to children, salt reduction strategies, using existing policies designed for combating micronutrient deficiency to simultaneously address the obesity problem by promoting local fruits and vegetables via local farm networks. Another major initiative is the Global Strategy on Diet, Physical activity, and Health action plan aimed at prevention and control of NCDs between 2013 and 2020. The action plan resulted from a multi-stakeholder consultation process consisting of the WHO member states, relevant UN agencies, funds and programs, international financial institutions,

banks, NGOs, professionals, academicians, the civil society, and the private sector [126]. It operationalizes the tasks articulated in the Political Declaration of the General Assembly's initiative on the prevention and control of NCDs. The action plan focuses on four major chronic diseases, namely, cardiovascular disease, cancer, chronic obstructive pulmonary disease, and diabetes; several chronic conditions, e.g., mental illness; disabilities; and four shared behavioral risk factors – tobacco use, unhealthy diet, physical inactivity, and harmful use of alcohol [126–128]. While the WHO leads and coordinates the plan through engagement, international cooperation, and collaboration, the individual governments are responsible for action and monitoring. The overarching principles are as follows:

1. Highest quality and standard of health is a fundamental human right.
2. Social determinants of health should be addressed to create equitable, productive healthy societies.
3. Member governments and international agencies should create alliances and foster high-level multi-sectoral engagement.
4. A life course approach starting at preconception moving through healthy aging in later life will lead to sustainable health outcomes.

5. Communities should be engaged at all stages of planning, implementing, evaluating, and monitoring to ensure empowerment and motivation for sustained success.
6. Evidence-based and/or experiential-based best practices that are cost-effective, affordable, and culturally congruent should be implemented.
7. All segments of the society should have access to safe, affordable, effective, and quality-based promotive, preventive, curative, and rehabilitative services.

2.6 Conclusion

It is apparent that NCDs are the most pressing challenge at the present time. They pose a threat to healthy aging for global communities, irrespective of their stage of socioeconomic development. At the same time, it is important to not lose sight of the communicable and nutritional deficiency diseases that persist across large segments of the globe. It is important to recognize that malnutrition at either end of the spectrum is distinctive in etiology and physiological manifestations yet, in fact two sides of the same coin. Undernutrition and overnutrition share certain common risk factors and are multifactorial in their etiology, and the need for their control and prevention cannot be underscored.

Health is a state of complete harmony of the body, mind and spirit. When one is free from physical disabilities and mental distractions, the gates of the soul open.
–B.K.S. Iyengar, yoga master

3

Learning Objectives

- Current "normal" has transitioned away from genuine wellness.
- Genuine wellness must remain the plumb line for human wellness.
- Salutogenesis is an important foundation for wellness healthcare.

3.1 Introduction to Human Wellness

Have you noticed the trend to perceive type 2 diabetes as a "normal" condition after age 50? Have you noticed the trend to perceive a little arthritis pain in the joints as a "normal" condition after age 40? These conditions have become so prevalent that adults are trending to consider these conditions as the "normal" for states of health. The "normal" today in this time of epidemic chronic disease is promoting amnesia of true wellness.

3.2 What Is Wellness?

Wellness certainly means freedom from the debilitating, weakening effects of chronic disease. As a side product of this level of wellness, one feels dynamic, energetic, alive, vital, and vibrant. From this healthy state, we can respond effectively to environmental stress, toxins, or infections, quickly returning to our previous state of health and wellness [1].

Health and vitality refer to your life energy and the power to live, grow, know the purpose in life, and express your maximum potential as a human being. Individual lives are made up of many facets, all interconnected. Nutrition provides the energetic and physical foundation for achieving wellness as defined by Hershoff in all its dimensions.

Before exploring the principles surrounding restoration of wellness from chronic disease, it is important to recognize that we must set a clear vision of the health goals for each patient. Throughout human history, humanity has faced many challenges in the search for health and longevity, and people have culturally developed ways of life to function successfully. There is ongoing speculation by experts in human biology that the current state of global health is being challenged by the beginning of declining lifespan [2, 3] and fertility [4].

It is important that we identify the biomarkers that define and characterize the human wellness we are striving to restore in our patients. The "normal" of current populations has already deviated significantly from states of wellness. There is no better example than the current epidemic of obesity that is being predicted as the twenty-first century begins: Upwards of three-fourths or more of industrialized countries' populations are predicted to be obese (>30% ideal body weight) by 2030 [5]. In 1962, research statistics showed that 13% of America's population was obese. By 1980 it had risen to 15%, to 23% by 1994, and to an unprecedented 39.8% of adults by 2016. According to the Centers for Disease Control and Prevention, the percentage of overweight children ages 6–11 has nearly doubled since the early 1980s, while the percentage of overweight adolescents has almost tripled [6]. These overwhelming research statistics reveal an alarming obesity trend, the need for diagnosis, and a call to action [7, 8] (Fig. 3.1).

CDC research statistics on American obesity tell us that 63% of adult Americans and 18.5% of children and adolescents have a body mass index (BMI) in excess of 25.0 and are therefore overweight; more than a quarter surpass 30.0, qualifying as obese [9]. Obesity is becoming the "norm," even

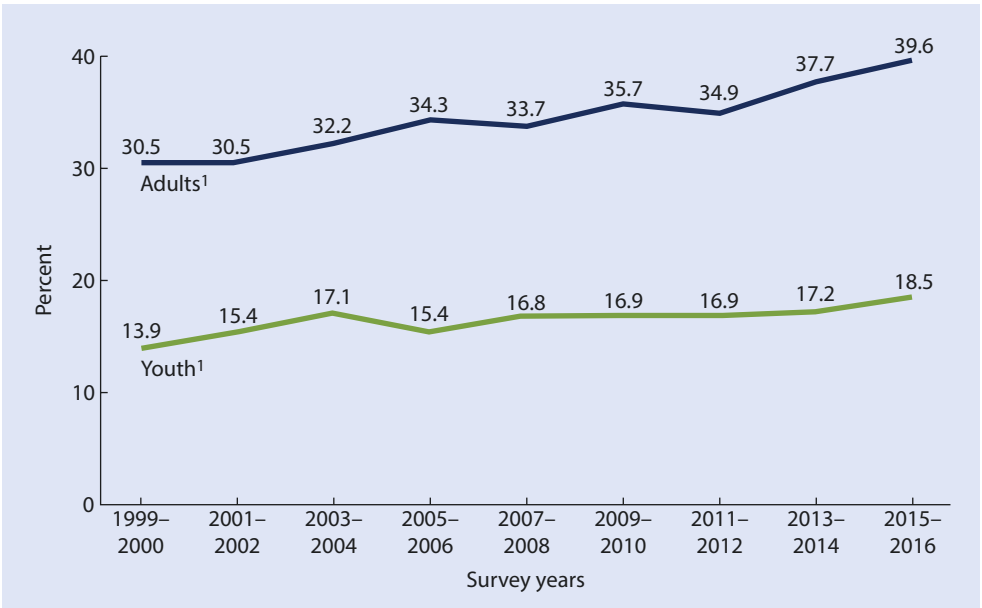

Fig. 3.1 Trends in obesity prevalence among adults aged 20 and over (age-adjusted) and youth aged 2–19 years: United States, 1999–2000 through 2015–2016 (Hales 2017). [1]Significant increasing linear trend from 1999–2000 to 2015–2016. NOTES: All estimates for adults are age adjusted by the direct method to the 2000 US census population using the age groups 20–39, 40–59, and 60 and over. Access data table available at ► https://www.cdc.gov/nchs/data/databriefs/db288_table.pdf#5. (SOURCE: NCHS, National health and Nutrition Examination Survey, 1999–2016)

though it is not an example of wellness. That is a staggering thought when we realize the relatively short period of time during which this epidemic has occurred. Obesity is strongly related to the incidence of chronic disease. As the obesity trend increases, human models of wellness are becoming rarer. Humans tend to gravitate toward acceptance of what is prevalent as "normal" and may tend to forget the real wellness we are seeking to restore. Health practitioners must keep the definition of true wellness before them as a standard with which to compare their patients.

3.3 Biomarkers of Wellness

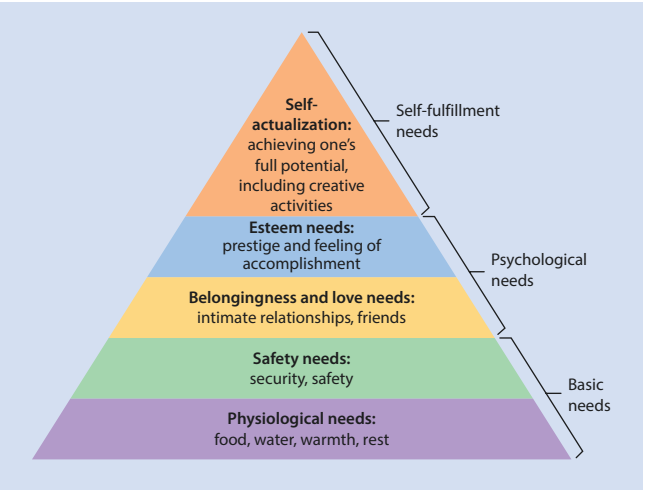
What are the biomarkers for wellness? This chapter presents suggestions for a framework for markers to assess wellness, for which further development is welcome. At least it is a good foundation developed from many studies in the last century that evaluated common characteristics of human populations who achieved excellent function, life fulfillment, and good reproduction capacity during their relative longevity. Currently, it is proposed within the longevity science community that a 115-year lifespan is a realistic goal [10].

Thanks to the efforts of various scientists in the past 70 years, there has been research stimulated by scientific curiosity regarding the populations who have stretched longevity and wellness to the upper limits. Humans confirmed to have attained the age of 110 years or more are referred to as *supercentenarians*. Identifying factors that help people remain healthy, vigorous, and disability-free at older ages is a major research priority of longevity scientists. The most recent study is that of Dan Buettner named *The Blue Zones* – those pockets of societies with the most healthy centenarians and generally healthy populations [11].

Common factors that have measurable biomarkers among the healthiest societies are repeatedly found to be:

1. Unprocessed, whole foods, plant-rich diet (diet history; nutrient status)
2. Caloric and nutrient intake so as to maintain a healthy Weight (anthropometrics)
3. Regulating insulin production [12] (blood glucose/insulin fasting; HgbA1C)
4. Moderate daily physical activity (minutes per day or week; handgrip strength)
5. Small amount of alcohol frequently (daily female </= 1 serving; men 1-2 servings daily)
6. Strong community and social connectivity (1–10; 10 highest)
7. Meditation and spiritual beliefs (time per week)
8. Feeling of purpose in life (1–10; 10 highest)

The diets of these longevity-rich societies vary according to cultural traditions, but all contain a high intake of whole vegetables and fruits and beneficial food oils. Interestingly, these foods are rich in the phytonutrients, the most recently identified nutrient group [11].



Self-actualization: achieving one's full potential, including creative activities
Esteem needs: prestige and feeling of accomplishment
Belongingness and love needs: intimate relationships, friends
Safety needs: security, safety
Physiological needs: food, water, warmth, rest
Self-fulfillment needs
Psychological needs
Basic needs

Fig. 3.2 Hierarchy of needs

> The way you think, the way you behave, the way you eat, can influence your life by 30 to 50 years. –*Deepak Chopra*

Throughout the community of integrative and functional medicine practitioners' concepts like Maslow's hierarchy of needs have developed [13] has agreement that the following factors are key influencers that summarize the findings of many studies on longevity and wellness:

"Basic needs": Biological, physiological, and safety needs

1. Foods (protein, fats, carbohydrates, fiber)
2. Vitamins, minerals, accessory, or conditionally essential nutrients
3. Light, water, and air
4. Movement rhythm
5. Circadian rhythm balance
6. "Mind-body needs": Love, belongingness, self-esteem, cognitive, aesthetic, and self-actualization needs
7. Meaning and purpose
8. Love, community, connection

All seven are inherently interrelated in the context of the human experience that affects wellness (Fig. 3.2).

3.4 Biochemical Individuality/Health Standards Through the Lifespan

As the professional rules of thumb for nutritional status assessment are developed in subsequent chapters, it will be seen that the environmental conditions necessary to produce the identified markers of wellness are biochemical, clinical, behavioral, and functional and change throughout developmental stages of the lifespan. The following are some of the primary stages of the lifespan with suggestions for considerations to assess and manage to promote wellness for each stage. These are of particular importance to increase the health of a person and their nutritional status within the area of chronic disease management:

3.4.1 In Utero

- Fetal nutrition: promote healthy musculoskeletal-organ-tissue fetal growth
- Maternal:
  - Hormonal health: adrenal, thyroid, insulin, and others
  - Blood glucose management
  - Emotional environment: calm and joyful
  - Rest: adequate rest, sleep, and exercise
  - Nutrition status: adequate vitamin D25-hydroxy, iodine, DHA, iron, folic acid, protein, minerals, beneficial oils, antioxidants, and phytonutrients, to promote good growth and protect tissue from free radical damage [14]
  - Avoid toxin exposure
- Grandmaternal nutrition status: same as mother, avoidance of toxins to avoid epigenetic transgenerational effects
- Paternal nutrition status: important 2 years prior to conception, avoid toxins, and especially 14 days prior to fertilization

3.4.2 Infant (From Birth to 6–24 Months)

- Breastfeeding infant nutrition: promote healthy musculoskeletal-organ-tissue fetal growth
- Maternal lactation and caretaker:
  - Emotional environment: calm and joyful
  - Rest: adequate rest, sleep, exercise
  - Hormonal health: adrenal, thyroid, insulin especially
  - Nutrition status: adequate vitamin D25-hydroxy, iodine, DHA, iron, protein, minerals, antioxidants, and phytonutrients to promote good growth and protect tissue from free radical damage and adequate fluid intake
- Home environment: stable, caring, joyful
- Infant 6 months + oral nutrition: balanced organic whole foods, hypoallergenic diet
- Infant:
  - Vaccination wisdom
    1. Never when sick
    2. Wait until 4+ months if possible
    3. Mercury- and formaldehyde-free
    4. Extra nutritional antioxidant support and folic acid prior to a vaccination
    5. Consider vaccination alternatives for at-risk infants with poor methylation family history or genetics
  - Safe sun exposure for vitamin D production (never burn)
  - Fresh air and exercise and play

3.4.2.1 Toddler (12–36 Months)

- Positive parenting.
- Seriously consider vaccination need/avoid unnecessary/mercury- and formaldehyde-free.
- Child safety environment.
- Nutrition: Regular meals of organic/low-toxin food containers and nutrient-dense, balanced whole foods.
  - Protein
  - Calcium- and mineral-rich foods
  - Nuts/seeds
  - Fish or fish oils/EFA balance
  - Whole grains
  - Sea salt/herbs/spices
  - Fruits and vegetables
  - Onions/garlic (sulfur/bioflavonoid)
  - Cruciferous vegetables (sulfur/indole-3-carbinol)
  - Leafy greens (folic acid, chlorophyll, magnesium, etc.)
  - Fermented or cultured foods (yogurt/kefir/sauerkraut/miso/tempeh)
  - Sea vegetables (iodine/minerals)
  - Vitamin A- and D-rich foods/supplements if indicated
- Sun exposure (promote Vitamin D) (or supplementation cod liver oil >40° latitude).
- Play and exercise.

3.4.2.2 Childhood (3–12 Years)

- Continue toddler recommendations.
- Educational programs.
- Self-esteem-building lifestyle.
- Nutrition: Ensure adequate protein/calcium/minerals for rapid musculoskeletal growth – possible increased needs during this growth period.
- Sun exposure almost daily – cod liver oil during winter if >40° latitude.
- Develop food preparation self-skills.
- Develop hygiene practices – especially oral and dental care habits.
- Sleep: 9–10 hours with bedtime routine/quiet and dark environment.
- Focus on oral/dental care: avoid mercury amalgams, orthodontics that include removal of teeth, as well as prevent periodontal diseases and decay by daily dental hygiene and regular dental cleanings.

3.4.2.3 Teenage (13–19 Years) (◘ Fig. 3.3)

- Continue childhood nutrition recommendations.
- Strong family base/good relationships with parents and teachers.
- Avoid "junk food" and "toxin exposure" (cigarettes, drugs, environmental).
- Possible need for extra sleep.
- Weight-bearing regular exercise (peak time for bone density building for adulthood).
- Develop advanced food preparation and self-care skills.
- Creative outlets for interests.
- Begin to develop purpose in life.
- Abstinence/avoid communicable diseases/avoid birth control pills (upsets hormonal balance, depletes folic acid).

Fig. 3.3 Teenage energy and vitality. (2005© Diana Noland)

- Focus on oral/dental care: avoid mercury amalgams, orthodontics that include removal of teeth, as well as prevent periodontal diseases and decay by daily dental hygiene and regular dental cleanings.

3.4.3 Young Adult (20–34 Years)

- Continue teenage nutrition recommendations.
- Whole foods; low-toxin organic foods, containers, and cookware; balanced, nutrient-rich diet.
- Moderate daily exercise.
- Avoid toxins.
- Seriously consider vaccination need/avoid unnecessary/mercury- and formaldehyde-free.
- Prepare health for possible pregnancy or fathering – even if not planning. Caution about use of birth control pills (BCP) related to the nutrient-drug depletions of folic acid, magnesium, zinc, and other B complex vitamins to promote select malnutrition (i.e., those depleted in folic acid are at more risk for HPV infection which is related to increased sexual activity, more prevalent with use of BCP).

3.4.3.1 Middle-Age Adult (35–54 Years)

- Continue young adult recommendations with nutrition focus.
- Focus on nutrition to support healthy aging with phytonutrients, healthy fatty acid balance, minerals, methylation and sulfation nutrients, and hormonal and immune support nutrition like vitamin D.
- Focus on oral/dental care: avoid periodontal diseases/decay/misalignment.
- Continue to focus on weight-bearing exercise to maintain good bone density throughout the lifespan.

3.4.3.2 Seniors (54–74 Years)

- Continue to focus on nutrition to support healthy aging with phytonutrients, healthy fatty acid balance, minerals, methylation and sulfation nutrients, and hormonal and immune support nutrition like vitamin D.
- Focus on gastrointestinal health as digestive function wanes naturally in elderly.
- Good oral hygiene and health.
- Maintain healthy percentage of body fat composition and weight.
- Weight-bearing exercise.
- Emphasize social connectedness, especially around food quality and meal time.
- Stress management.
- Adequate sleep.

3.4.3.3 Old-Old Seniors [15] (75–99 Year)

- Continue to focus on nutrition to support healthy aging with phytonutrients, healthy fatty acid balance, minerals, methylation and sulfation nutrients, and hormonal and immune support nutrition like vitamin D.
- Focus on gastrointestinal health as digestive function wanes naturally in elderly.
- Weight-bearing exercise.
- Safe environment to meet basic needs.
- Emphasize social connectedness, especially around food quality and meal time.
- Maintain healthy percentage of body fat composition and weight.
- Weight-bearing exercise.
- Continue to focus on nutrition to support healthy aging with phytonutrients, healthy fatty acid balance, minerals, methylation and sulfation nutrients, and hormonal and immune support nutrition like vitamin D.
- Safe environment to meet basic needs.
- Residential support system with family or caring friends (▶ Boxes 3.1 and 3.2).

Box 3.1 Key Markers of Childhood Wellness

- No cavities
- Sturdy
- Strong
- Cheerful disposition
- Not overweight
- No allergies
- Manages stress
- Emotionally stable
- Sleeps soundly
- Straight teeth
- Learns easily
- Good concentration
- Optimistic
- Lots of energy
- Rarely sick
- Strong digestion

Box 3.2 Key Markers of Human Wellness

1. HEALTHY BODY WEIGHT: +/− 10%; %BODY FAT: M < 18%/F < 25% with no observable central adiposity
2. HEALTHY SKIN: color, tone, texture, free of lesions, abnormal moles, itching, pain
3. HEALTHY DIET: balanced whole foods and low-toxin diet, water
4. HEALTHY EMOTIONS: caring, social connectedness, relationships, purpose in life, self-esteem, community/family involvement, appropriate emotions
5. HEALTHY ORGAN SYSTEMS FUNCTION: including blood glucose management resulting in stable insulin blood levels
6. HEALTHY IMMUNE SYSTEM: infrequent illness, illness only of mild nature with quick recovery, absence of chronic disease, absence of allergies
7. HEALTHY MOVEMENT: adequate energy and ability to exercise, run, jump, play, and lift appropriate weight, no pain
8. HEALTHY MUSCULOSKELETAL: Strong grip, strong muscles for walking and running, no aches and pain, no broken bones or sprains
9. HEALTHY REPRODUCTION/FERTILITY: Throughout lifespan normal gonadal development, fertile, no pain with menses (F), no STDs, sexual health, healthy birth delivery, symptom-free menopause
10. HEALTHY GASTROINTESTINAL SYSTEM: 2–3 BM/day, good digestion, no flatulence
11. LONGEVITY to >110 years old with high-quality function and life
12. LOW-TOXIN exposure lifestyle

3.4.3.4 Centenarians/Supercentenarians (100+ Years)

- Emphasize social connectedness, especially around food quality and meal time.
- Maintain healthy percentage of body fat composition and weight.
- Weight-bearing exercise.
- Continue to focus on nutrition to support healthy aging with phytonutrients, healthy fatty acid balance, minerals, methylation and sulfation nutrients, and hormonal and immune support nutrition like vitamin D.
- Safe environment to meet basic needs.
- Residential support system with family or caring friends.

3.5 Nutritional Wellness

Nutrients come from food, and food comes from the environment. While taken for granted at an intellectual level, this nutrient-food/food-environment relationship is not something citizens of industrialized nations usually consider in their everyday lives [16]. Consumer awareness of food-toxic harmful events over the past 30 years due to media reporting has increased consumer food safety concerns. The increasing frequency of recalls of contaminated food, findings of animals with "mad cow disease," chickens with avian flu viruses, the fish supply testing high in mercury and PCBs, endocrine disruptors, and others presents a growing concern for the quality of the food supply. The message is coming through loud and clear to society that environment plays an integral part in food safety.

The human community must ensure safe food and agricultural practices as a priority in this new era of toxicity, superbugs, and depleted soils, ensure to reverse trends, ensure environmental safety of the food supply, and enable humanity to have wellness within its grasp.

A nutritional environment for wellness results from an attitude of guardianship over the food supply. A wellness environment requires a global food supply of diversity in geography, climate, exposure to toxins, and many other variables. It involves ensuring the food is not depleted and does not contain dangerous level of toxins [17]. The food that produces wellness requires human care in policies and agriculture in every stage from soil to plate.

3.6 Community of Wellness

Throughout history, humans have been brought together around the table, a symbol of congregation, family, and community, where we celebrate loved ones. Food is a central part of a healthy community. It provides not only bodily nourishment but also nourishment to the soul from the care taken in raising, gathering, and preparing the food and in the relationships and connectedness forged and strengthened during the meal. In the larger community of a nation, the societal mores about food and the wellness of the population affect people's health. It is important to elevate the societal value of health and wellness within global communities so they guard the soil, water, food supply, food industry, healthcare systems, and governmental policies. The tremendous knowledge of human metabolism gained by each generation has the potential to positively influence populations to improve every individual's opportunity to be well and live a full life. There is an imminent need for an alignment of society's thinking with the newer discoveries of nutrition science to implement lifestyle basics and policies that are key to thriving in wellness.

Salutogenesis is a concept that literally means "that which gives birth to health." It is a term that has not been well known since its creation by Antonovsky in 1979 [18]. In traditional public health and community medicine approaches, the focus is the opposite: on disease or illness and its prevention or treatment. This latter focus most often dominates interventions. In the communities where longevity and quality of life are most prevalent, the culture of salutogenesis prevails. Adoption of a salutogenic perspective highlights the importance of starting from a consideration of how health is created and maintained. Contrary to industrialized societies where medical care and "healthcare" focus on "pathogenesis," salutogenesis is the inverse [19].

The salutogenic paradigm needs to suffuse all members of a community as it focuses on the promotion of global well-being rather than the origins of specific disease processes. The focus on wellness strategies and lifestyle choices empowers individuals to experience the full spectrum of the human experience. A community of interconnected individuals and families is necessary to activate the force of wellness and develop the ability to empower others to lead salutogenic lives and to transform our culture into one of worldwide wellness.

3.7 Summary

- True wellness achieves a life that is dynamic, energetic, alive, vital, and vibrant.
- Salutogenesis is a paradigm of a healthcare approach of how to create and maintain health.
- Twelve markers of human wellness.
- The healthiest societies on earth have a good diet and lifestyle in common.

4.1 Introduction

Barely a year into the United Nations Decade of Action on Nutrition, the global community of researchers and practitioners in nutrition and associated fields has its work cut out. Malnutrition, which includes overnutrition, undernutrition, and imbalanced nutrition, affects at least a third of the earth's population and is by far the greatest contributor to the global burden of disease [1]. For the period 2014–2016, it is estimated that more than 794 million people (10.9% of the world population [2]) were undernourished and concurrently 2.1 billion were overweight or obese [3]. Both overweight and underweight are significantly associated with premature death [4], as are many other diet-related factors including excess sodium intake and micronutrient deficiencies [5]. Every year, more than 3 million children die of causes related to undernutrition [6], and in 2010 alone, overweight conditions and obesity are estimated to have resulted in 3.4 million deaths [3].

To appreciate the scale of these statistics, consider that the 3.4 million deaths attributed to overweight and obesity in 2010 is 1432 times the number of airline fatalities in the worst-ever year of commercial aviation disasters (1972) and 42 times the *total* number in 74 years of commercial aviation history [7]. It is equivalent to 6800 jumbo jets fully laden with 500 passengers each – 18 jets for every day of the year. Adding childhood deaths due to undernutrition, and we are staring in the face of what amounts to 12,800 fatal jumbo jet crashes a year, or 35 daily. Aviation-related losses would not be allowed to reach a small fraction of these numbers; in fact, since 1978 they have steadily decreased, notwithstanding the steep increase in the numbers of flights [7].

A question that is increasingly attracting attention is why have we not done a better job of preventing illness and deaths due to malnutrition? There are many views, but four themes repeatedly emerge. First, nutritional behavior and its causes and consequences are highly complex [8, 9], and the dominant models of nutrition research and practice do not pay sufficient respect to its complexity [10–12]. Second, nutrition is an intrinsically interdisciplinary problem requiring expertise from many areas – e.g., chemistry, physiology, and psychology to economics, law, and politics – but insufficient attention is paid to this fact in the training of nutrition scientists. Third, a systems perspective is needed to bring together the diverse parts of the complex multifaceted nutrition system and to identify how they interact to determine the important outcomes. Finally, we need to evolve a food and nutrition system that respects optimization goals beyond minimum cost and maximum pleasure and profit, including human health, equity, and planetary sustainability. Considerably less well-developed than the articulation of where we have gone wrong in nutrition are concrete suggestions for how we can implement a systems-based interdisciplinary agenda in nutrition science and practice to put the problem right.

In this chapter, we introduce a field from the natural sciences, called nutritional ecology, which we believe can contribute toward bridging the gap between the food and nutrition system that we currently have and the system we would prefer. We begin by clarifying how we use the term "nutritional ecology" to place it in the context of related approaches. We then discuss some biological insights from nutritional ecology that we think can make a significant contribution to nutrition research and practice and thereafter introduce a geometric framework for implementing this theory. We end with examples showing how the implementation of biological thinking via nutritional geometry can provide a concrete step toward a fresh, systems-based, view of human nutrition.

4.2 "Nutrition" and "Ecology"

An important first step is to define what is meant by the term "nutritional ecology" as used in the ecological sciences (and this chapter) and how it relates to the use of the same term and the closely related term "nutrition ecology" in human nutrition.

4.2.1 Human Nutrition

In human nutrition, the first published use of either term of which we are aware was in a collection of essays titled *The Feeding Web: Issues in Nutritional Ecology* [13], which examined the impacts on health and ecological sustainability of the industrialization of the US and global food systems. Elaborating on this approach, the term "nutrition ecology" was introduced in 1986, referring to an "interdisciplinary scientific discipline that incorporates the entire food chain as well as its interactions with health, the environment, society, and the economy" where the food chain encompasses "production, harvesting, preservation, storage, transport, processing, packaging, trade, distribution, preparation, composition, and consumption of foods, as well as disposal of waste materials along the food path" [14]. Nutrition ecology is considered a new nutrition science [15], which differs from conventional human nutrition science in two key respects. Firstly, it takes a broader view that extends beyond nutritional biology to encompass also societal and ecological issues. Secondly, it emphasizes interdisciplinary systems science as a framework for dealing with the broad scope of the subject [16].

Nutrition ecology is considered to also be distinct from the field of "nutritional ecology" that has developed in the ecological sciences and anthropology [16]. We are, however, unaware of any explicit discussions on the similarities and differences between the nutritional ecology frameworks in these fields. Since "nutritional ecology" sensu the ecological sciences has recently come to focus on humans [12, 17], as the closely related framework in anthropology has done for some time now (see below), it is worth briefly examining how this term is used in those two fields.

4.2.2 Ecology and Anthropology

An early use of the term "nutritional ecology" is Schneider (1967) [18]. While based in the clinical and public health-related field of nutritional immunology [19], this prescient paper advocates the use of experimental designs in epidemiology derived from "an analysis of the problem in ecological concepts that goes beyond classical concepts in the fields of nutrition and microbiology" [18]. As we discuss below, this adumbrated a central defining feature of the ecological field of nutritional ecology, namely, the importance of applying ecological and evolutionary theory to understand the nutritional biology of animals [20].

The earliest use of the word term "nutritional ecology" that we could locate in the ecological literature is a treatise on grasshopper ecology, published in a 1962 volume of the Memoirs of the Indian Museum [21]. Relevant subsequent uses include Von Goldschmidt-Rothschild and Lüps (1976) [22] and Stanley Price (1978) [23]. The subjects of these publications could not have been more different from the context in which Gussow (1978) [13] used the term in relation to industrialized human environments. The study of Von Goldschmidt-Rothschild and Lüps (1976), for example, examined the extent to which domestic cats in Switzerland prey on small game birds, by dissecting the gut contents of 257 cats that had been shot while hunting [22]. Stanley Price's study assessed the nutritional status of wild hartebeest [23]. As in Von Goldschmidt-Rothschild and Lüps' cat study, Price did this by dissecting out the gut contents of shot animals but went further by measuring the nutritional composition of the eaten foods. He also performed digestion trials that compared the nutrient content of food eaten by captive hartebeest and sheep with the nutrient content of the feces they produced. Given how disparate Stanley Price's study is from Gussow's book, which appeared in the same year, it is not surprising that these works did not refer to each other, and neither did Gussow refer to any of the earlier ecological studies nor Schneider's (1967) paper [13, 18, 23]. This suggests that the term "nutritional ecology" was probably derived independently in nutritional immunology, human nutrition, and ecology.

Over subsequent years, "nutritional ecology" became established as a subfield of ecology in its own right, being applied across animals in general, including insects [24], mammals [25], birds [26], and fish [27], as well as plants [28]. Nutritional ecology in this sense has been defined as "the science of relating an animal to its environment via nutritional interactions" [29]. These interactions involve behavioral and physiological aspects of food and nutrient acquisition and their relationship to the health, growth, and reproduction of animals [30]. A strong emphasis is on the ways that individuals adapt to nutrition-related aspects of the environment, which takes place across various timescales from short-term homeostatic responses to environmental changes, through developmental adaptation and Darwinian adaptation by natural selection [31].

The term "nutritional ecology" has been used in anthropology in much the same way that it developed in ecological sciences [32]. Jenike (2001) defined it as "…the interaction of diet, somatic maintenance, physical activity, and pathogenic agents as they relate to growth, body composition, development, and function in a constraining social, political and natural environment" [32]. This definition was modified by Hockett and Haws (2003), who defined the approach as "… the study of the relationship between essential nutrient intake and its effects on overall human health, including growth and maintenance in individuals and general demographic trends in populations" [33]. Both definitions share, in common with the ecological sciences, an emphasis on the individual within the context of the environment.

4.2.3 Nutritional Ecology and Human Health

The origins of nutrition ecology (in human nutrition) and nutritional ecology (in the ecological sciences and anthropology) thus differed, with the former being focused more on the broader human nutrition system and the latter on the individual within that system. In the terms of ecological science, this broadly reflects the difference between the sub-fields of community ecology (emphasis on community-level issues, such as food webs) and functional ecology (emphasis on the characteristics of individuals that adapt them to their environments) [34]. This difference is not, however, absolute, but more an issue of emphasis. Nutrition ecologists do not exclusively consider the social and environmental dimensions of nutrition, but also the biological dimension [15]. Likewise, nutritional ecologists are aware of the importance of the biological characteristics of individual organisms in shaping the ecological communities within which they exist [20, 35]. Issues of emphasis are, nonetheless, important because they influence the questions, theory, and methods that direct progress in a scientific field.

In the remainder of this chapter, we demonstrate using our own work how the biological theory and methods from nutritional ecology can provide new insight into human nutrition and its links to health [12]. The perspective that we bring derives from almost three decades of research into the nutritional ecology of non-human organisms, ranging from slime molds, yeast, and insects in laboratory studies to giant pandas, monkeys, gorillas, and orangutans in the wild [36]. We do not view this approach to be an alternative to nutrition ecology, but rather a means to expand human nutrition science to integrate the interests and expertise of nutrition ecology with the biological theory and the comparative perspective of nutritional ecology.

4.3 The Importance of Appetite

Among the most emphatic messages to emerge from our studies of non-human animals is that appetite is paramount for understanding foraging, feeding, and its impacts on the

animal and, ultimately, on the community of which it is a part. This might seem obvious, except that biological theory combined with studies on the nutritional ecology of non-human animals has provided a more nuanced and powerful concept of appetite than currently exists in human nutrition science.

In this section, we summarize the biological background to the nutritional ecology view of appetite and, in the following section, introduce an approach for modeling and measuring appetite in this sense. Thereafter, we show how these models can help to integrate appetite within the broader human nutrition system to help bridge the gap between the biological theory and methods of nutritional ecologists and the integrative goals of nutrition ecology [15].

4.3.1 Multiple Appetites

To appreciate the subtleties of appetite, we need to step back and ask the question "what is appetite for?" This is a good stage to point out that the "what for?" question is a hallmark of the evolutionary framework on which nutritional ecology is based; it aims to understand biological traits partly through knowledge of what they evolved to achieve [37]. The power of this approach is that it provides an expectation of, firstly, how the biological trait should be designed to achieve its evolved function and, secondly, how it should respond in various circumstances. For example, it can help to understand how the human appetite works and how it might respond to the industrialized food environments of which Gussow (1978) wrote in the book that first used the term "nutritional ecology" in the context of human nutrition [13].

The simple answer to the question "what is appetite for" is that it evolved as a "control center" that directs the animal to meet its nutritional needs, in the same way that thirst directs it to drink and the sensation of cold causes shivering and heat-seeking behavior. To achieve its purpose, however, appetite should be considerably more complex than motivations such as thirst or temperature-related discomfort, for several reasons. First, thirst and temperature regulation have simple endpoints (sufficient hydration and optimal temperature, respectively), whereas an animal's nutrient needs are complex, involving many nutrients, each required at its own particular level. Second, the relative needs for different nutrients change over time and with the circumstances of the animal; for example, female birds have elevated protein and calcium requirements for producing eggs [38], whereas more fat and carbohydrates are needed to fuel the costs of long-distance migration [39]. Meeting multiple and changing nutritional needs in this way, in complex and changing environmental circumstances, is a substantial challenge.

An animal could not deal with this challenge if it had only a single appetite that, for example, caused a bird to eat the same diet regardless of whether reproducing or preparing for migration, any more than we would expect a motor car to have only a single warning light that did not distinguish between an oil and gasoline shortage. Theory therefore predicts that animals should have separate appetites for specific nutrients to help ensure that they eat the specific blend of nutrients that is appropriate for their particular needs at a given time. Such "nutrient-specific appetites" are known to exist for many animals, including humans (see ▶ Sect. 4.5). Although the details of which nutrients are regulated by specific appetites are expected to differ with the ecological and evolutionary circumstances of different species, the universal importance of the macronutrients protein, carbohydrates, and fat means that most animals have separate appetites to regulate either two or all three of these [36]. Some also have specific appetites for the minerals calcium [40] and sodium [41].

4.3.2 Appetites Interact

Important as they are, the possession of nutrient-specific appetites is not on its own sufficient to ensure that animals satisfy their nutrient needs [42]. An added complexity is that most nutrients are not available separately in the environment, but come packaged in mixtures called foods. If a food contains the same ratio of different nutrients as is needed by the animal – for example, high protein relative to carbohydrate and fat when reproducing – then the complex nature of foods is a benefit, because this enables the animal to satisfy its requirements for all nutrients from one source. It is, however, seldom the case that the composition of foods exactly matches the mix of nutrients needed, and this complicates nutrition considerably, both for animals and for attempts by nutritional ecologists to understand animal nutrition.

Where possible, animals deal with this challenge through "complementary feeding," in which specific combinations of nutritionally imbalanced foods are mixed in the right proportions to balance the diet overall. This requires that the appetites for the different nutrients cooperate to ensure that each is eaten at a level that meets, but does not exceed, the respective requirements. Many animals have been shown to balance their diets in this way, both in laboratory experiments and in the wild [36], and so too do humans (see ▶ Sect. 4.5.1).

In reality, however, ecology is not always so obliging as to provide combinations of complementary foods that can be mixed to obtain a balanced diet. Rather, animals often find themselves in situations where the only foods available restrict them to eating a diet that is imbalanced with respect to their nutrient needs. For example, many primates that need both fruits, which are high in sugars and fats, and protein-rich leaves to balance their diet, endure periods of fruit scarcity in which they are forced to eat a leaf-rich diet containing excess protein [43].

In this situation, the appetites for protein and non-protein energy enter into conflict, because the target intakes for both cannot be achieved simultaneously. Rather, the nutritional options available to the animal are to eat the target level of protein and suffer a shortage of non-protein energy, to eat the target level of non-protein energy while overeating protein,

or to settle on an intermediate outcome in which it has both a moderate excess of protein and a moderate shortage of non-protein energy. Research has shown that different species resolve this competition between appetites in different ways, which likely reflect the relative costs of under- or overeating the two nutrients [36].

While such interactions between appetite systems are complex, they are also extremely important for understanding how diet influences the behavior, the physiology, and the health of animals. To help simplify the challenge, we have invented a modeling approach called the Geometric Framework for Nutrition (GFN). In the following section, we introduce the basic concepts of GFN and show how they have been applied to understand macronutrient regulation in humans.

4.4 From Concepts to Models: Introduction to the Geometric Framework for Nutrition

The value of the ecology- and evolution-inspired concepts from nutritional ecology is substantially enhanced if these concepts can be expressed in quantitative models. Quantitative models provide a framework within which the various relevant factors can be measured and their relationships explored to interpret the ways in which they interact to influence important outcomes such as energy intake and health [44]. We now demonstrate how the nutritional ecology ideas from the previous section can be modeled using the simple geometry of GFN (Fig. 4.1). Thereafter, we show how these models have been applied to understand macronutrient regulation and its consequences for energy intake in humans.

4.4.1 Model Selection

The first step in constructing a GFN model is to select the nutrients that are relevant to the problem under investigation. In so doing, special care should be taken to heed the dictum attributed to Einstein that "things should be as simple as possible … but no simpler": we should include in the model only those nutrients that we suspect play an important role in the problem, but ensure that all of the nutrients that do so are included. A common problem in human nutrition science is the tendency to attribute outcomes such as obesity to individual nutrients, usually fats or carbohydrates, without regard for how they interact with other nutrients in exerting their influence [12, 45] (please see ▶ Chap. 8).

Since our example concerns obesity, we will focus on the energetic macronutrients protein, fat, and digestible carbo-

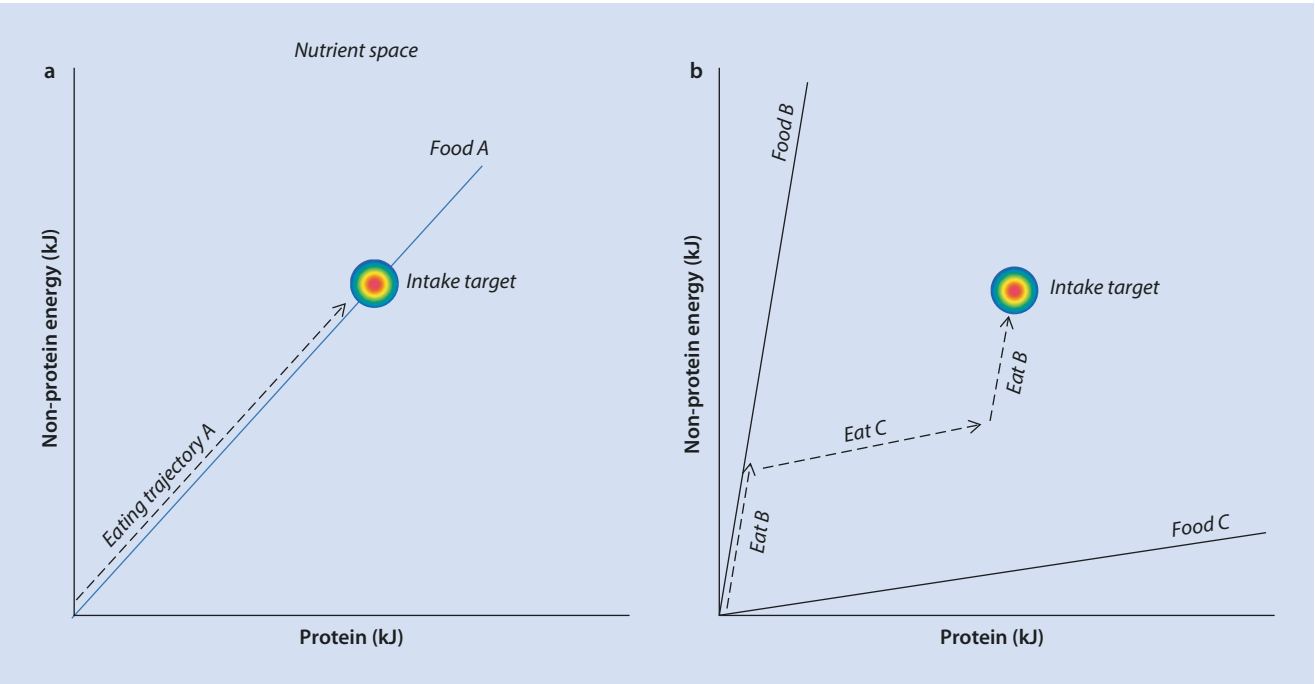

Fig. 4.1 Basic concepts in the Geometric Framework for Nutrition. The "nutrient space" is the space formed by the two nutrient axes, in this hypothetical model protein (horizontal) and combined fats and digestible carbohydrates (non-protein energy) [vertical]. An "intake target" is plotted within the nutrient space, representing the amount and balance of nutrients (in this case protein and non-protein energy) that are targeted by the animal's regulatory systems. Foods are represented as lines, called "nutritional rails," which originate at the origin and project into the graph at angles that represent the ratio of the nutrients that each contains. As the animal eats, it ingests the nutrients in the same ratio as they are present in the food it is eating, and its nutritional state thus changes along a trajectory identical to the rail for that food. The animal can therefore reach its intake target either by selecting a food that has the same ratio of nutrients as the intake target (i.e., a nutritionally balanced food) (food A, in **a**) or by switching between foods that are individually imbalanced but together nutritionally complementary (foods B and C in **b**)

hydrates, although in different contexts we might be interested in other nutrients (e.g., [46]). We will also initially simplify the model by combining fats and carbohydrates into a single category to address the question of how the human appetite for protein (P) interacts with non-protein energy (henceforth NPE) to drive energy intake (Fig. 4.1). Our reasons for doing this are that, firstly, in some contexts, fats and carbohydrates can be regarded as interchangeable sources of metabolic energy for humans [47] and, secondly, as we show in the next section, when all three macronutrients are considered in their own right, distinguishing fats and carbohydrates in the data that we present as an example does not provide a better explanation for energy eaten than does considering them combined. We note, however, that in many other contexts – for example, appetite interactions in mice [48] and the causes of cardiovascular disease in humans [49] – it is important to distinguish fats and carbohydrates and even the different sub-categories of these nutrients. Geometric models can readily be applied in this context.

Having selected the nutrients of interest, the next step is to make a graph where each nutrient is represented on its own axis, as shown in Fig. 4.1. Here, too, there is an important decision to make, regarding the units in which to represent the different nutrients – for example, whether mass (grams) or energy (kilojoules). In our model, we have chosen energy units, because the aim is to understand how different blends of macronutrients influence energy intake.

We have now constructed a *nutrient space*, which provides the platform on which we model how the appetites for different macronutrients interact to influence energy intake (Fig. 4.1).

4.4.2 Selecting an Intake Target: Nutritionally Balanced and Complementary Foods

An important reference point in modeling appetite interactions is the *intake target*, or the point in nutrient space that shows the amounts and balance of the nutrients that the appetite systems will target under circumstances in which they are unconstrained by the quality or quantity of available food (Fig. 4.1). Theory predicts, and studies have shown, that in many cases the selected intake target provides a diet that optimally satisfies the animal's needs for the different nutrients [50–52]. The animal is able to reach its intake target through the appetites for the different nutrients working in harmony to meet the respective intakes that are best for the animal.

The way that the animal satisfies its nutrient needs is, of course, by eating foods, but the important question is *which* foods the animal can eat to reach its intake target. To examine this, we can plot in the model the composition of various foods, as lines called *nutritional rails*, which project from the origin into the nutrient space at an angle determined by the ratio of the nutrients that each contains. As the animal eats, it ingests the nutrients in the same ratio as is contained in the food it is eating. Its nutritional state can therefore be viewed as "moving" through the nutrient space at an angle equivalent to the rail for the food it is eating and over a distance determined by how much of the food it eats. Figure 4.1a shows that food A contains the same ratio of the nutrients as does the intake target (the rail passes through the intake target), and in the spatial metaphor of the model, the animal can therefore "navigate" to the target by eating this food (feeding trajectory A in the figure). This food is thus *nutritionally balanced* with respect to the animal's requirements for protein and non-protein energy.

Foods B and C, by contrast, do not pass through the intake target – they are *nutritionally imbalanced* with respect to P and NPE (Fig. 4.1b). However, since food C contains too much P relative to NPE (falls to the right of the target) and food B too much NPE relative to P (to the left of the target), the two foods are nutritionally *complementary* and can be combined in appropriate proportions to provide a balanced diet. Complementary feeding is shown in the nutrient space as a zigzag trajectory, where each leg represents an amount eaten of the respective foods (Fig. 4.1b).

4.4.3 Negotiating a Compromise: When the Intake Target Cannot Be Reached

Animals can therefore reach their intake target by selecting balanced foods (e.g., Fig. 4.1a) or mixing their intake from nutritionally complementary foods (Fig. 4.1b). What options does the animal have when confined to a single nutritionally imbalanced food or non-complementary combination of imbalanced foods? As discussed above, in this case the target point cannot be reached for both nutrients, and the appetite systems need to negotiate a compromise that minimizes the cost to the animal of its dietary predicament. Such strategies are known as *rules of compromise*.

A distinguishing feature of GFN is that it enables us to model the various rules of compromise and thereby to understand the strategies that animals have evolved to deal with dietary imbalance. Figure 4.2 shows three examples, representing extreme responses chosen from a wide range of possible strategies [36, 53]. In the blue strategy, protein wins over entirely – the animal eats to the point on the nutritional rail where its need for P is met, regardless of whether NPE is under-eaten (on high P:NPE diets) or overeaten (on low P:NPE diets). This pattern, known as *protein prioritization*, has been observed in wild spider monkeys [54] and orangutans [55]. The green strategy is the opposite, namely, prioritization of non-protein energy, where P is over- or under-eaten to meet the NPE target. This pattern is shown by wild mountain gorillas, which overeat protein to obtain the target level of fats and carbohydrates in periods when fruit shortage commits these animals to a high-protein diet [56]. It is has also been observed in several carnivores, including mink [57] and predatory beetles [52]. The red strategy represents the situation where neither nutrient group dominates over the other, but the appetite systems give equal weighting to

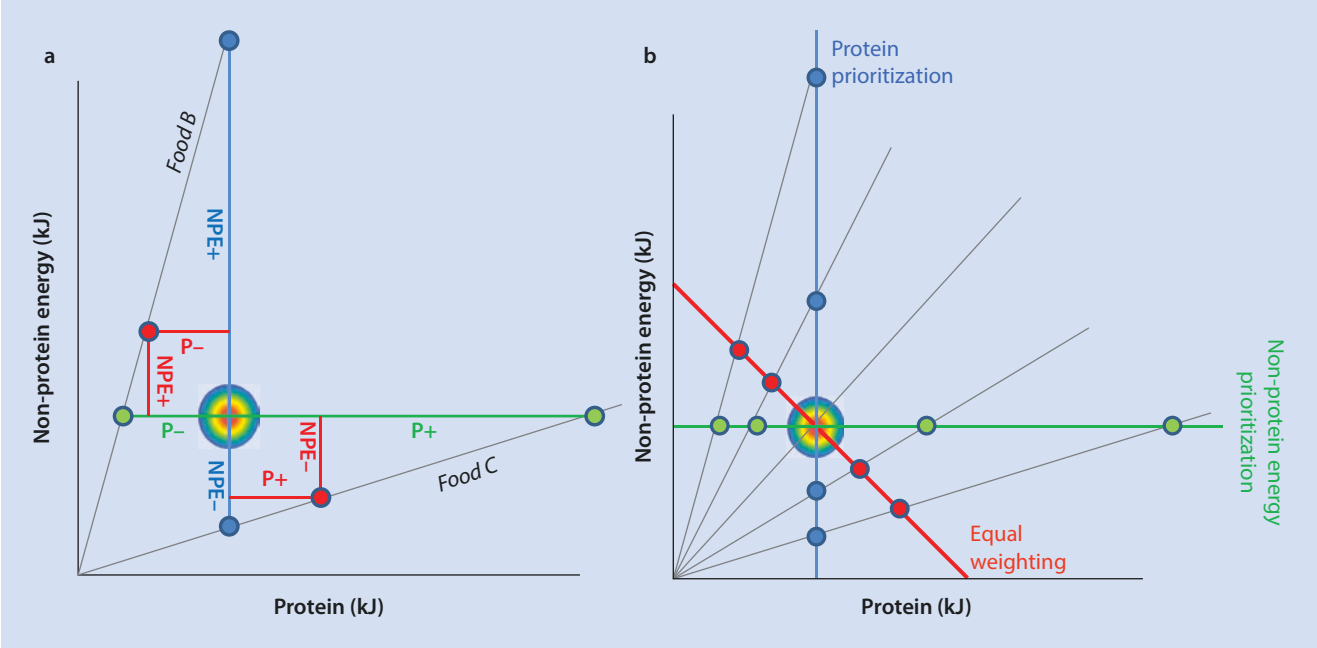

Fig. 4.2 **a** Schematic showing geometric representation of possible regulatory responses to nutrient imbalance. When confined to a single nutritionally imbalanced food (i.e., with a rail that doesn't intersect the intake target), the animal needs to resolve a trade-off between over-ingesting one nutrient and under-ingesting the other. By feeding to the green point, it meets its target for non-protein energy (NPE, comprising fats and carbohydrate combined) at the cost of suffering a shortage of protein of magnitude P- on low P:NPE diets (e.g., if restricted to food B) or a protein excess (P+) on high P:NPE diets (food C). The converse would be true if the animal ate to the blue points – it would meet its protein target, but to do so would have to ingest an excess or deficit of NPE (NPE+ and NPE-, respectively). By feeding to either of the red points, the animal would meet its target for neither nutrient, but would ingest a moderate excess of NPE and a deficit of P on food B or a moderate excess of P and a deficit of NPE on food C. **b** Testing different experimental groups, each on one of a range of foods varying in nutrient balance, provides a description of how the animal resolves the trade-off between over- and under-ingesting nutrients when confined to imbalanced foods, termed a rule of compromise (ROC). Three possibilities are illustrated: the blue symbols represent absolute prioritization of protein (i.e., feeding to the target coordinate for protein regardless of whether this involves over- or under-eating NPE), the green symbols represent NPE prioritization, and the red symbols represent an intermediate response in which the regulatory systems assign equal weighting to excesses and deficits of the two nutrients (P– = NPE+ on food B and P+ = NPE- on food C). Many other configurations are possible

each: it eats to the point on the imbalanced nutritional rail where the ingested excess of one nutrient exactly matches the deficit of the other. This pattern has been observed in wild rhesus macaque monkeys [58] and several species of generalist-feeding herbivorous insects [36].

4.5 The Geometry of Nutrition in Humans: Protein Leverage

How do humans regulate macronutrient intake, and can this help to understand obesity? These questions have been addressed in several independent studies, including randomized control trials [59–61], analyses of data compiled from the literature [62], and survey data of human populations [63–65]. Results of these studies have consistently highlighted the importance of appetite interactions in driving energy intake.

4.5.1 Do Humans Select an Intake Target?

A recent study has addressed this question, with striking results. Following protocols developed by Gosby et al. (2010), Campbell et al. (2016) presented 63 Jamaican volunteers with 3 menus from which to select a diet over 3 days within a residential experimental facility [61, 66]. All 3 menus contained the same 29 dishes, but the compositions of the dishes were manipulated using added protein and carbohydrate such that all options on one menu had 10% of energy from protein, a second had 15%, and a third had protein at 25%. Fat was held constant at 30% for all dishes and menus. Since the human diet seldom contains less than 10% protein or more than 25%, we reasoned that if an intake target exists, then it lies somewhere between these extremes and can be reached by composing a diet from the experimental menus through complementary feeding. The menu with 15% protein represented our best guess at what the composition of the target diet is, because this is close to the mean intake levels found in Western diets [67].

Results are plotted in Fig. 4.3. The three solid radial lines are nutritional rails representing the compositions of the experimental menus, and the blue-shading shows the area that could potentially be reached by subjects in this experiment. Despite the wide range of possibilities, it is striking that all subjects, whether male or female, clustered tightly around a line representing 14.7% protein, although males ate

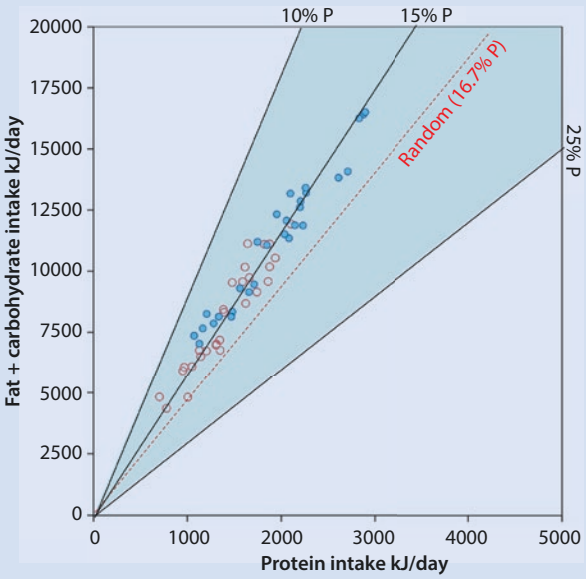

Fig. 4.3 Daily protein and non-protein energy intakes self-selected by 63 adult Jamaican volunteers, averaged for each subject over the 3-day experimental period. Red symbols are females, and blue symbols are males. The solid radial lines are nutritional rails representing the compositions of the three experimental menus from which the diets could be freely selected (10, 15, and 25% protein by energy). The pale blue region represents the range of diets that could theoretically be selected from these menus, and the dotted red line represents the expected outcome if the subjects mixed the diets randomly (16.7% P). The data show that subjects selected a diet of 14.7% protein, which was significantly different from the random outcome. (Adapted from Campbell et al. [61]. With permission from Creative Commons License)

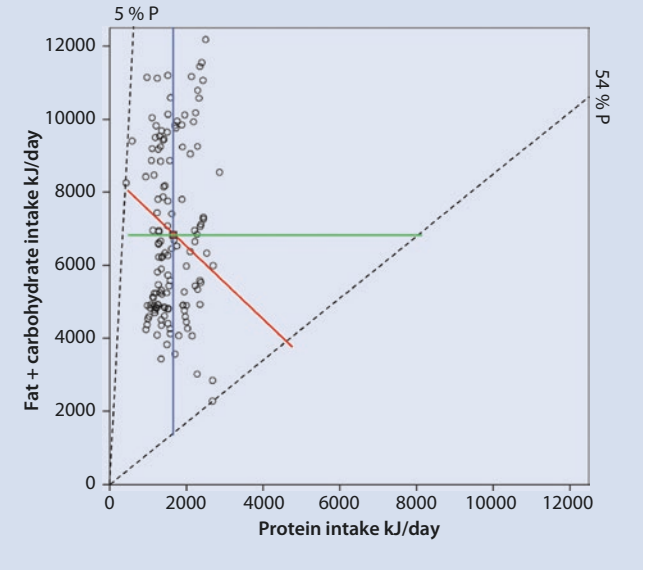

Fig. 4.4 Interaction of human appetite systems with dietary macronutrient ratios. Data are protein (x-axis) and non-protein (fat + carbohydrate, y-axis) ad libitum energy intakes by subjects restricted to 1 of 138 experimental diets [62, 69]. The black dashed radials represent the nutritional rails for the diets with the highest (54%) and lowest (5%) proportional protein content. The area between these radials is the region of the nutrient space within which points for nutrient intakes are constrained to lie, with the pattern of actual intakes being determined by the ways that appetites for protein, fat, and carbohydrate interact. The blue, red, and green lines represent the protein prioritization, NPE prioritization, and equal weighting models from Fig. 4.2. The analysis shows that humans maintain absolute protein intake relatively tightly, with non-protein energy intake varying more passively with dietary macronutrient ratios. (Adapted from Raubenheimer and Simpson [12]. With permission from Annual Reviews)

more of the diet overall than females, which is not surprising given their larger body size.

One possible explanation for this pattern is that the subjects did not distinguish between the three diets based on their macronutrient content, but simply ate equal amounts of each. It can be calculated that if this were the case, the intake points would align along the dashed radial line, representing a diet with 16.7% protein. However, the actual intakes differed with a high degree of statistical certainty from this line, showing that they represent macronutrient regulation to a P:NPE intake target. An earlier experiment by Simpson et al. (2003) showed similar results [68].

4.5.2 What Is the P:NPE Rule of Compromise in Humans?

Several studies, including randomized control trials [59, 60, 68], analyses of experimental data compiled from the literature [62], and observational studies using diet surveys [63], have addressed the question of how humans respond to macronutrient-imbalanced diets. Since the results all tell the same story, we will present only the data of the literature compilation of Gosby et al. (2013), as expanded by Raubenheimer et al. (2015) [62, 69].

What all of these studies in the compilation have in common is that each experimental subject was restricted to one of a range of single diets, each with fixed P:NPE ratio, and allowed to eat as much of their respective diet as they wished. The experiments therefore test how the human appetite systems interact to determine protein, fat, and carbohydrate intake as dietary macronutrient balance varies – i.e., the rule of compromise for these nutrients. The result is shown in Fig. 4.4. Protein intake remained relatively stable over a wide range of diet compositions, while the intake of fats and carbohydrates increased with decreasing dietary P:NPE ratio. Humans thus show the protein prioritization pattern of macronutrient regulation (Fig. 4.2).

This analysis shows that information about the dynamics of human appetite systems is essential for understanding why we eat the amounts of nutrients and energy that we do. The main conclusion that it presents is by no means obvious: it suggests that humans will overeat fats and carbohydrates not because they have a particularly strong drive to eat these nutrients, but because of a strong appetite for *protein*. On the other hand, we should not interpret this to suggest that the human appetite is exclusively about protein. We know that this is not the case, because when allowed to select a diet from nutritionally complementary foods, humans regulate

the intake of both P and NPE (Fig. 4.3). Rather, in circumstances where it is possible, the appetites for different macronutrients cooperate to select a balanced diet, but when limits on available foods prevent this, protein regulation overrides and fat and carbohydrate intakes follow more passively.

This phenomenon, where the appetite for protein influences the intake of other nutrients such as fats and carbohydrates, has been termed *protein leverage* [47].

4.6 Beyond Appetites

Our discussion to this point illustrates the logical progression of research within the nutritional ecology framework. We began by showing that evolutionary and ecological reasoning predicts that animals should have separate appetites for different nutrients and that these appetite systems should interact to determine nutrient intakes. We then introduced nutritional geometry as an approach for measuring such appetite interactions and demonstrated how it has been applied to humans. Results showed that the humans in our study selected an intake target of approximately 15% energy from protein, and when restricted to macronutrient-imbalanced diets that prevented them from achieving this target, they showed the protein prioritization rule of compromise, in which fats and carbohydrates are passively over- or under-eaten as the percentage of dietary protein varies.

This is, principally, an examination of organismal (in this case human) biology, which, as we commented above, is an important starting point for nutritional ecology research. The next step is to expand the model to understand how the trait, in this case appetite interactions, engages with broader aspects of the animal's nutritional biology, including specific nutrient requirements and the food environment that nutrition ecologists have emphasized in their writing.

One hypothesis that addresses this is the *protein leverage hypothesis* (PLH) [47]. PLH proposes that the protein prioritization pattern of macronutrient regulation has interacted with reductions in the P:NPE ratio of the human diet to drive fat and carbohydrate overconsumption and obesity. This hypothesis can potentially provide a powerful bridge between human biology, modern human environments, and health because, if true, it simplifies the search for the causes of the obesity epidemic. It does this by focusing attention on a very simple question about the role of environmental change in driving this epidemic: *what is the cause of protein dilution in the human diet that leads our appetite systems to overeat fats and carbohydrates?*

Simple questions are not, however, necessarily simple to answer, and this is no exception. Like human biology, modern industrialized human food environments are extremely complex, and the interactions between human biology and modern environments potentially all the more so. To help deal with this complexity, we have adopted from nutritional ecology a form of nutritional geometry called the right-angled mixture triangle (RMT); [70]) (Fig. 4.5). In the remainder of this chapter, we introduce the RMT and demonstrate in the context of the protein leverage hypothesis how it can provide an aid for understanding the biology-environment interactions that influence health in industrialized food environments.

4.6.1 The Geometry of Mixtures: Three Components in Two Dimensions

As its name implies, the RMT is an approach for modeling mixtures. The axes are therefore scaled as the proportional (or %) contribution of each nutrient to the overall mixture, rather than absolute amounts, as is the case in the GFN models of appetite interactions (e.g., kilojoules eaten per day, as in Figs. 4.3 and 4.4). The key difference between these two variants of nutritional geometry is thus that one is proportions-based and the other is amounts-based. Beyond that, they share much in common and are, in fact, complementary approaches for modeling nutrition.

As is the case for amounts-based geometric models, the first step in building an RMT model is to decide which nutrients are most relevant to the problem. Since we are extending the analysis of how macronutrient appetites interact to influence energy intake, we will include in our model the macronutrients protein, fats, and carbohydrates expressed in energy units. An important advantage of the RMT approach, however, is that it enables all three nutrients to be modeled in a simple two-dimensional graph. Amounts-based geometry can also cope with more than two nutrients, but generally only by simplifying the model (e.g., combining two nutrients into a single axis, as for fats and carbohydrates in Figs. 4.3 and 4.4) or else by plotting three two-dimensional graphs (protein vs. fat, protein vs. carbohydrates, and fat vs. carbohydrates).

To illustrate how three components are represented in a two-dimensional RMT, consider the black point in Fig. 4.5a, representing the macronutrient composition of a sample of rice. The percentage contribution of protein to total macronutrient energy in the rice is 5% (x-axis) and of fat is 10% (y-axis). Since % protein + % fat + % carbohydrate must add up to 100% of macronutrient energy, it is easy to see that % carbohydrate = 100 – (%protein + %fat) = 100 – (5 + 10) = 85. Geometrically, 85% carbohydrate is represented by a diagonal line that connects the same value on the x- and y-axes and intersects the point representing the sample of rice. Any mixture of macronutrients that comprises 85% of energy from carbohydrates will fall on this line, which is plotted in the figure as the black dotted diagonal labeled "85."

By the same logic, it can be seen at a glance that the peas in the plot comprise 25% of energy from protein, 5% from fat, and 70% from carbohydrate, and the steak comprises 40% protein, 60% fat, and 0% carbohydrate.

4.6.2 A Hierarchy of Mixtures

Just as the macronutrients combine in specific proportions in foods, so too do foods combine into meals, meals into diets,

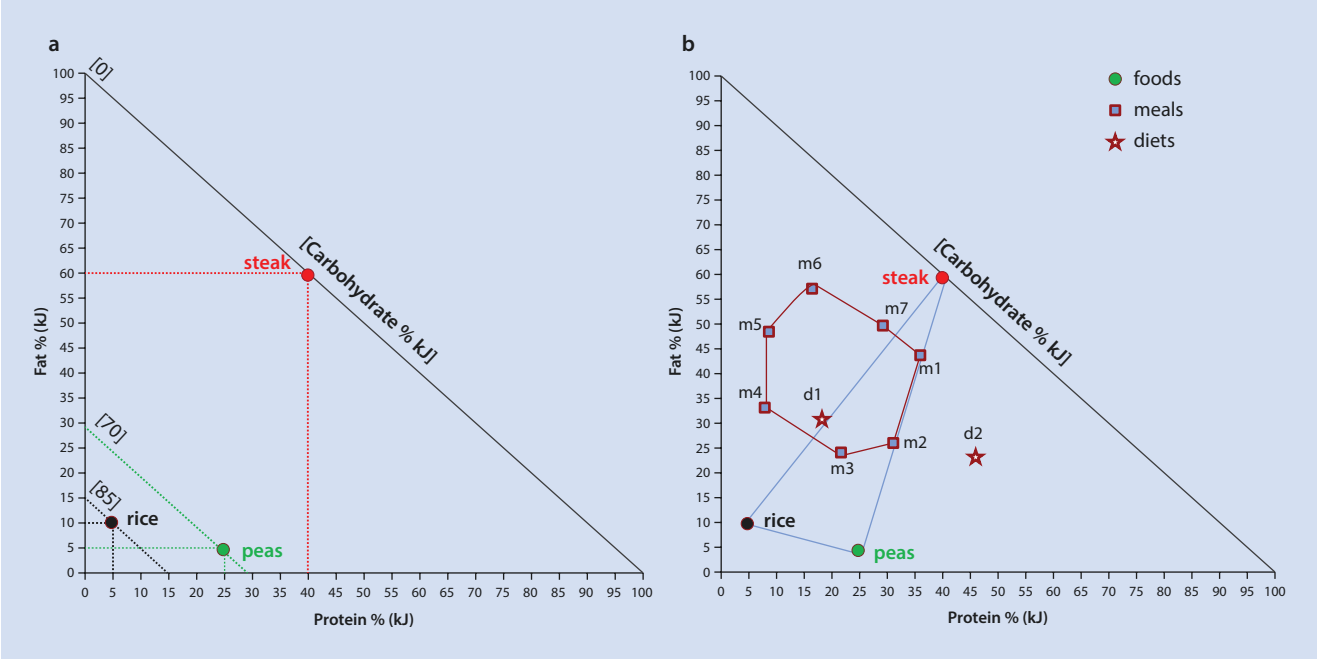

Fig. 4.5 **a** Right-angled mixture triangle [70] illustrating how components (in this case the macronutrients) combine into foods (rice, peas, and steak). Points represent the percentage contributed by each component (protein, fat, and carbohydrate) to the sum of the three. Thus, the macronutrient composition of rice is 5% protein and 10% fat, and since protein, fat, and carbohydrate sum to 100%, carbohydrate = 100 – (5 + 10) = 85%. This value is represented by the negative dashed diagonal joining 15% on the x- and y-axes, such that any mixture of macronutrients containing 85% of carbohydrate will fall on that line. Likewise, the peas contain 25% protein, 5% fat, and 70% carbohydrate, and the steak contains 40% protein, 60% fat, and 0% carbohydrate. **b** Foods combine into meals (m1–m7), and meals combine into diets (d1 and d2). A meal composed of two foods (e.g., peas and steak) is constrained to fall on the line connecting those foods (e.g., m1 and m2), with the exact position along the line being determined by the proportion of the foods in the meal. Adding a third food (e.g., rice) expands the set of possibilities to a triangle (meals m1, m2, and m3 can be composed from the three foods, but m4–m7 cannot). By extension, diets d1 can be composed from meals m1 to m7, but d2 cannot. (Adapted from Raubenheimer and Simpson [12]. With permission from Annual Reviews)

and diets into dietary patterns. Recent work in nutritional ecology has emphasized the value of considering all of these levels for understanding the nutritional strategies of animals [71]. This is critically important in human nutrition, because each level in the hierarchy engages in different ways with the complex organism-environment interface of humans in industrialized food environments [12].

For example, nutrients, the base level in the mixture hierarchy, interact with physiology, by engaging taste receptors, appetites systems, and numerous physiological pathways relevant to health (e.g., the insulin signaling system). It is not, however, nutrients that we buy, but principally foods, and to understand our shopping choices, we need to consider also this level in the hierarchy. Although some foods are eaten directly, the greatest portion of the human diet is eaten as mixtures of foods, called meals. Meals, therefore, are important levels of focus for understanding human eating choices. And yet neither foods nor meals are the primary link between nutrition and health; for that we need to consider the long-term cumulative intakes of foods and meals, namely, diets. To close the circle, diets impact health and disease principally via their primary components, the nutrients.

A powerful aspect of RMT plots is that they can model all levels in this hierarchy of mixtures, as illustrated in Fig. 4.5b. Consider, for example, a meal comprised of two foods, peas and steak. The macronutrient composition of this meal is constrained to fall on the line connecting these foods, with the exact position determined by the proportions of the two foods in the meals. Thus, meal compositions labeled m1 and m2 are attainable from peas and steak, but m3–m7 are not. If additional foods are included in the diet, then the set of possible meal compositions expands to a space. For example, a meal consisting of peas, steak, and rice can take on any macronutrient composition that falls within the triangle formed by these foods (e.g., m3), but no composition that falls outside of the triangle (m4–m7). By the same logic, meal m1–m7 could combine into a weekly diet that falls within the polygon formed by connecting these meals (e.g., d1), but not outside of it (d2).

4.6.3 Dietary Macronutrient Balance

Distinguishing and interrelating different levels of the dietary mixture hierarchy in this way provides important benefits for examining the ways that human nutritional biology engages with industrialized food environments. However, to realize the potential of this approach, we need to move beyond describing mixtures such as foods, meals, and diets and examine how they link to human biology and to the food environments with which our biology interacts. An important first step is to relate these compositional data to nutrient requirements.

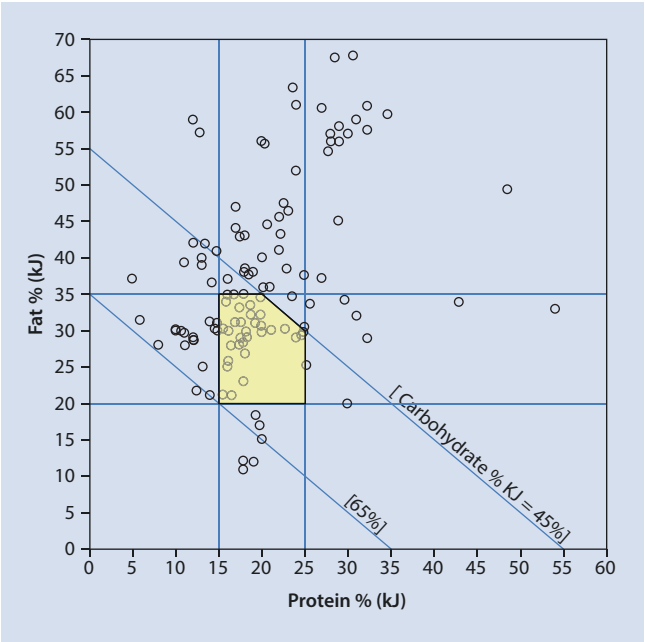

Fig. 4.6 Macronutrient compositions of the 138 experimentally fixed diets plotted from Fig. 4.4. The yellow polygon is an integrated representation of Australian/New Zealand Acceptable Macronutrient Distribution Range (AMDR; %P = 15–25%, %F = 20–35%, %C = 45–65%), such that diet points falling within this polygon represent macronutrient-balanced diets and those falling outside are macronutrient-imbalanced. (Adapted from Raubenheimer and Simpson [12]. With permission from Annual Reviews)

To illustrate, Fig. 4.6 presents in RMT format the same data as plotted in Fig. 4.4, representing the compositions of experimental diets compiled from the literature. As the figure shows, the data spanned a wide range of protein–fat–carbohydrate mixtures. To examine how these mixtures relate to proportional macronutrient requirements, we used for reference the Acceptable Macronutrient Distribution Ranges (AMDR) for Australia and New Zealand [72]. According to these recommendations, 15–25% of energy intake should come from protein, 20–35% from fat, and 45–65% from carbohydrate.

Delineating these individual ranges in Fig. 4.6 enables us to identify the region representing diets that satisfy all three recommendations, plotted as yellow polygon. Any diet with a composition that falls within the yellow region is thus macronutrient-balanced with respect to the AMDR, and any diet that falls outside is macronutrient-imbalanced.

4.6.4 Relationships Between Macronutrient Balance and Energy Intake

Central to the protein leverage hypothesis is the question of how energy intakes relate to dietary macronutrient ratios. We already have shown that low dietary protein leverages the intake of excess fat and carbohydrate and now address the implications for total energy intake. To do this, in Fig. 4.7, we have constructed a response surface onto the data from Fig. 4.6 that relates the ad libitum energy intakes (which was a voluntary response of the subjects) to macronutrient ratios of the diet (the experimentally fixed variable) [69].

The analysis shows that total energy intakes increased (intake values grade from blue to red) as the percentage of energy contributed to the diet by protein decreased (movement from right to left on the protein axis). This result substantiates the protein leverage effect shown in Fig. 4.4, but takes it further. First, it shows that the leveraging by protein of fat and carbohydrate intake (Fig. 4.4) translates into increased total energy consumption, as predicted by the protein leverage hypothesis. Second, energy intake changed as dietary protein varied (along the x-axis), but remained relatively constant along the fat axis. This suggests that, for these data at least, the main determinant of energy intake was the protein energy ratio (x-axis), with little effect of the relative proportion of fat:carbohydrate, and justifies our decision, discussed above, to combine fat and carbohydrate into a single axis (Fig. 4.4). Finally, plotting the data in this way helps to integrate additional factors into the model, such as energy balance.

4.6.5 Energy Balance

An important reference point for predicting the effects of protein leverage on obesity is Equilibrium Energy Intake (EEI), or the point at which energy intake matches energy expenditure. Energy intakes that exceed EEI signify positive energy balance and risk of fat accumulation, while lower intakes signify negative energy balance.

To incorporate the concept of energy balance into the model relating macronutrient ratios to energy intake, we estimated the EEI (given body size, sex, and expected activity levels under the experimental conditions) for the subjects from the experiments represented in the analysis to be 8813 kJ/day [69]. This value can be incorporated into the model as an EEI contour, represented in Fig. 4.7a as the bold dashed line. Intakes to the left of this line represent positive energy balance, and intakes to the right represent negative energy balance.

We can now relate across the experimental population dietary macronutrient balance (position in relation to the AMDR polygon) to energy intakes and energy balance, to predict the compositions of diets that will cause human appetites to drive energy overconsumption. An interesting feature of the model is that the EEI contour passes through the AMDR region. Assuming the same applies more generally within the relevant populations, this suggests that following the official New Zealand and Australian recommendations for proportional macronutrient intakes would spontaneously lead to balanced energy intake.

For comparison, we have also plotted in Fig. 4.7a the US AMDR [73]. The recommendations for carbohydrate and fat are the same as the Australian and the New Zealand AMDR, but the range for protein is broader, spanning 10–35% of energy intake. The model suggests that following the low end of the protein range (10–15% of energy intake from protein) would lead to energy overconsumption and

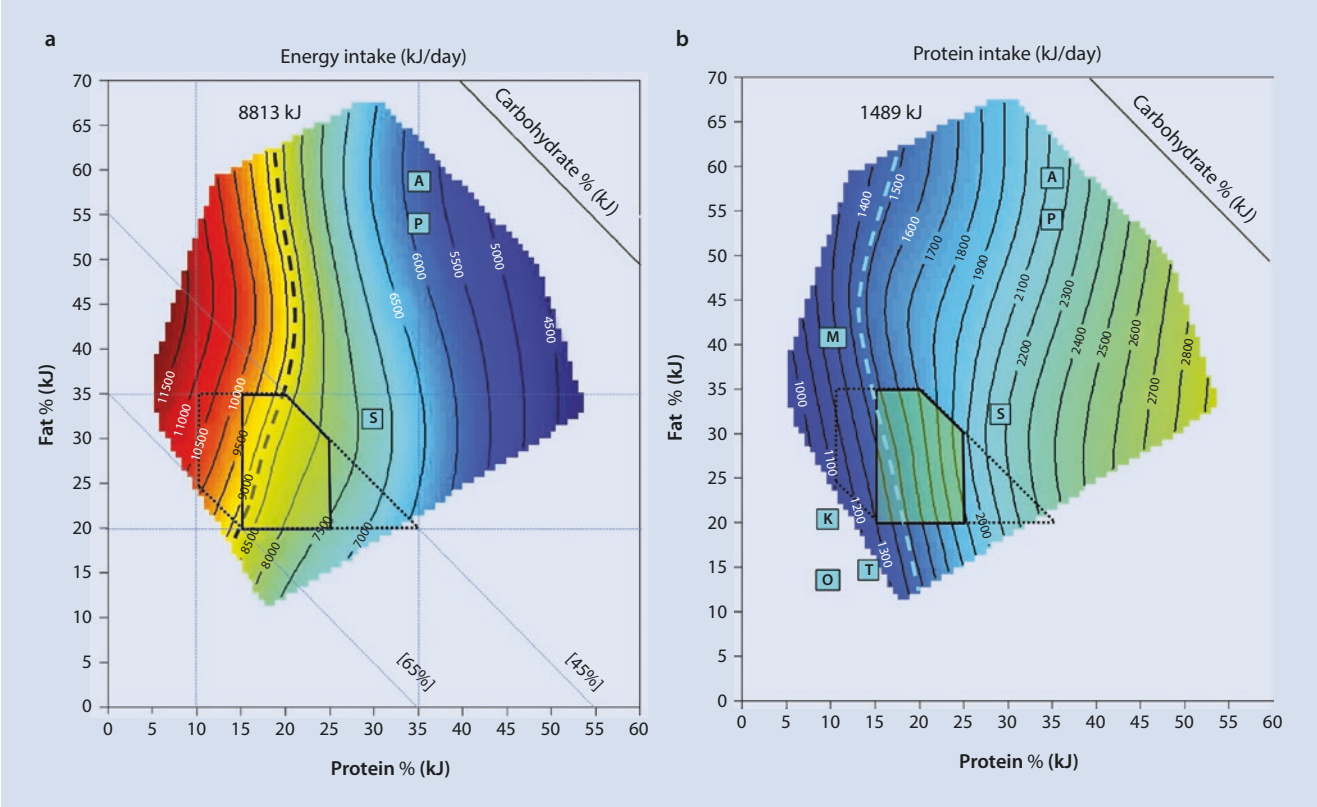

Fig. 4.7 **a** Response surface showing ad libitum daily energy intakes associated with the experimental diet compositions plotted in Figs. 4.4 and 4.6. The dashed contour represents estimated equilibrium energy requirements (8813 kJ) for sex and weight assuming a physical activity level (PAL) of 1.5, which is commensurate with activity levels in the experimental subjects. The data suggest that energy equilibrium was achieved on diets with 15–20% protein, with energy balance being negative and positive for diets with higher and lower % protein, respectively. The model is consistent with the association between weight loss and high-protein diets, such as the Atkins (A), Protein Power (P), and Sugar Busters (S) diets: their macronutrient compositions fall within the blue region of low ad libitum energy intakes. The dotted polygon represents the AMDR for the USA, which has the same ranges for fat and carbohydrate as the Australia/New Zealand AMDR, but a wider protein range (spanning 10–35%). **b** Response surface showing ad libitum protein intakes associated with the data in **a**. The dashed contour represents approximate average protein requirements for the study population (1489 kJ). The figure shows that protein intakes considerably higher than estimated requirements are associated with diets having macronutrient compositions equivalent to high-protein weight loss diets (A Atkins, P Protein Power, and S Sugar Busters). Conversely, low protein intakes are likely to be associated with the macronutrient composition of the diets associated with exceptionally healthy and long-lived human populations, the Mediterranean (M), Kitavan Islander (K), Tsimane (T), and traditional Okinawan (O) diets. (Adapted from Raubenheimer et al. [69]. With permission from The Obesity Society)

positive energy balance. In contrast, the high end of the US range for protein (25–35%) corresponds with low energy intakes and negative energy balance (the blue region). Indeed, the protein leverage effect can help to explain why many popular high-protein weight loss diets including the Atkins, Paleo, and Sugar Busters, which are shown in the figure, fall within this region.

4.6.6 Beyond Energy: Protein Intake

While the above analysis suggests a reason based on human appetite interactions (protein leverage) why high-protein diets are effective for weight loss (in the short term at least), we caution that low energy intake is not the only effect of consuming diets with high protein energy ratios. Another outcome is that compensation for the low levels of fats and carbohydrates results in protein overconsumption, albeit to a smaller extent than low protein leads to fat and carbohydrate overconsumption [12].

To illustrate, in Fig. 4.7b we have plotted the corresponding protein intake surface for the data shown in Figs. 4.6 and 4.7a. We have also calculated the Estimated Average Protein Requirements for the subjects in the experimental trials to be 1489 kJ and plotted this as a contour equivalent to the EEI contour in Fig. 4.7a. Viewing the data in this way clearly shows the increase in absolute protein intakes with increasing dietary % protein (left to right on the x-axis). It also shows that estimated dietary protein requirements are met for diets with approximately 15–20% protein energy, and at higher dietary protein densities, excess protein is ingested.

There is now strong evidence that excess protein intakes are associated with negative cardiometabolic profiles and accelerated aging, especially when coupled with low carbo-

hydrate intakes [45, 74]. Consistent with this is the observation that the healthiest dietary patterns, including the Mediterranean, traditional Okinawan [75], Kitavan Islanders [76], and Tsimane [77] diets, are associated with low dietary protein densities and low protein intakes, as shown in ◘ Fig. 4.7b. This should caution against high-protein diets, such as the Atkins, high-protein Paleo, and Sugar Busters diets (◘ Fig. 4.7), except as therapeutic interventions for weight loss. It also raises questions about the high end of the protein range sanctioned by the US AMDR.

In comparing ◘ Fig. 4.7a, b, the alert reader might have noted an apparent inconsistency. The Mediterranean, Kitavan Islander, traditional Okinawan, and Tsimane diets all have low protein energy ratios (between 10% and 15%) (◘ Fig. 4.7b) and under the model presented in ◘ Fig. 4.7a should thus be associated with excess energy intake, and yet obesity is not a problem within these societies. The reason for this apparent inconsistency is that the parameters of such models, including the shape of the surface relating energy consumption-to-macronutrient ratios, are population-specific and might be influenced by differences in nutrient and other aspects of the respective food environments. For example, the low-protein dietary patterns in ◘ Fig. 4.7b are associated with high fiber content compared with Westernized diets to which the model in ◘ Fig. 4.7a applies. High fiber is likely to induce satiety [78] at lower levels of protein (and energy) intakes than are low fiber diets [69], as has been demonstrated in mice [45]. The combination of low protein and high fiber thus has the double health benefits of limiting protein intake while avoiding energy overconsumption. The extension to consider also fiber emphasizes the importance of matching the model to the context and also demonstrates how these models can be built incrementally to incorporate multiple food constituents. Equally important is their extension to include broader components of the food environment, beyond diet composition.

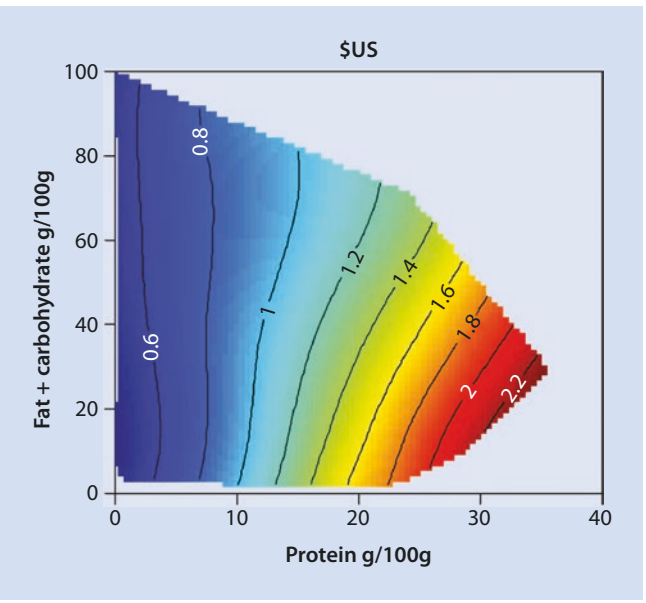
4.6.7 Interactions of Appetite with the Food Environment

To this point we have built a model that integrates human appetite interactions with a range of factors relevant to the relationships between diet and health, including the nutrient-food-meal-diet mixture hierarchy, dietary macronutrient ratios, intakes of energy and protein, recommended dietary macronutrient proportions and protein intakes, and energy balance. The model demonstrates one advantage of doing this: it helps to identify how these factors interrelate to explain the links between diet, health and disease.

Another advantage of building such a model is that it provides a context for identifying important aspects of our food environment that might influence the relationships within the model. For example, among the most salient and influential aspects of industrialized food environments is economics, giving rise to the question of whether the cost of foods might play a role in influencing the macronutrient composition of our diets. To address this, Brooks et al. (2010) calculated the relationship between the concentration (g/100 g) of protein, fats, and carbohydrates and the cost (in US dollars/100 g) of 106 supermarket foods [79]. Results showed that the cost of supermarket foods is positively related to their protein content (◘ Fig. 4.8). This suggests that economic considerations might be one factor that contributes toward diluting dietary protein content in industrialized food environments, an influence that our model has shown is transduced via the protein leverage effect into increased energy intake. In this way, protein leverage might help to explain the well-established association between lower socioeconomic status and obesity [80].

We might likewise address the question of why the USDA AMDR spans such a wide range of dietary protein densities, encompassing both low-protein diets (10–15% protein), which our model suggests are likely to be associated with excess energy intake (◘ Fig. 4.7a), and the high end (25–35%), associated with excess protein intake and premature aging (◘ Fig. 4.7b). One possibility is that this reflects influence on research and government policy by the food industry, rather than health considerations. For example, the sugar and affiliated industries selectively sponsor research that casts doubt on recommended upper limits to sugar intake, and the meat, dairy, and egg industries do the same for protein [81, 82]. These industries also exert influence on dietary guidelines through political lobbying [82].

Several other possible facets of industrialized food environments that might interact with human appetite systems to influence health have been identified. These include the influx of low-protein processed foods into the human food



◘ **Fig. 4.8** Relationship between the concentration (g/100 g) of macronutrients (protein, fat, and non-structural carbohydrates) and the cost ($US/100 g) of 106 supermarket foods. Cost increases from dark blue to red. The graph suggests that the cost of food increases with protein density but is unaffected by fat and carbohydrates. (Reprinted with permission from Raubenheimer et al. [17])

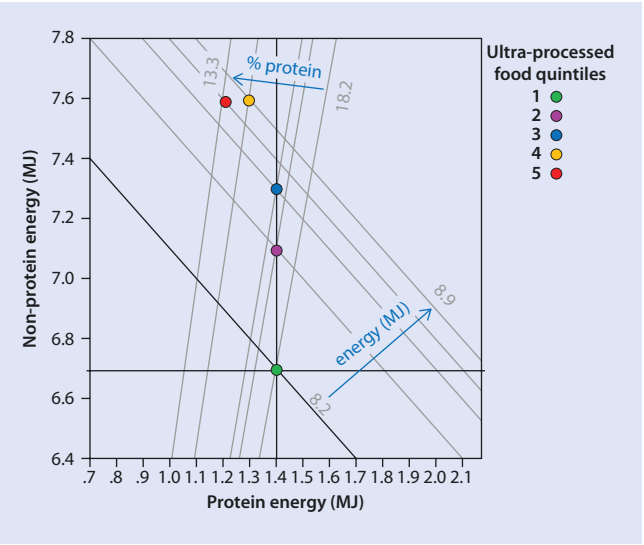


Fig. 4.9 Relationship between ultra-processed food consumption and protein leverage. The symbols represent protein and non-protein energy intakes for the lowest (green) to highest (red) quintiles of ultra-processed food (UPF) consumption reported in the National Health and Nutrition Examination Survey 2009–2010. The negatively sloped diagonals represent daily total energy intakes (calculated as the sum of X + Y), and the positive radials represent the dietary protein:non-protein energy ratio (X/Y). The dark vertical, horizontal, and diagonal lines represent alternative models to explain the data, as in Figs. 4.2 and 4.4. The data show that increased inclusion of UPF in the diet corresponds with reduced dietary protein density (18.3–13.3%) and increased total energy intake (8.2–8.9 MJ), as predicted by the protein leverage hypothesis. (Reprinted with permission from Martinez Steele et al. [64])

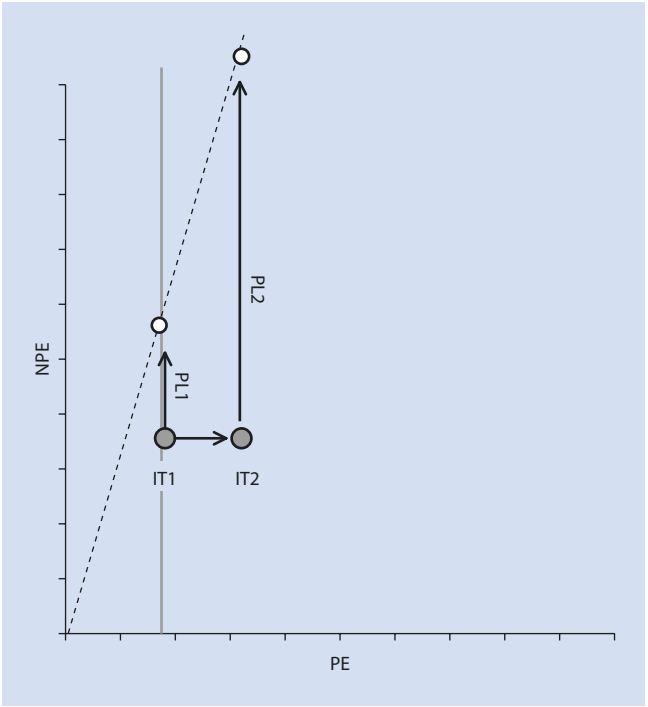

Fig. 4.10 Schematic showing the effect on protein leverage of an increase in the protein coordinate of the intake target, as might come about through decreased protein efficiency. The x-axis represents protein energy (PE) and the y-axis energy from carbohydrates and fat (NPE). The dashed radial shows the macronutrient composition of a food that has a lower PE:NPE ratio than intake target IT1. The arrow labeled PL1 denotes the extent to which surplus intake of carbohydrate and fat is leveraged by the mismatch between the PE:NPE ratio of the food relative to target IT1. For the same food, protein leverage is greatly exacerbated (PL2) for a small change in the protein coordinate of the intake target (IT1 increases to IT2). (Reprinted with permission from Raubenheimer et al. [17])

supply (Fig. 4.9) [64] and the reduction in plant protein that may be associated with rising atmospheric carbon dioxide [17], both of which could potentially have the effect of diluting the energy contribution of protein, thereby increasing energy intake.

In addition to such influences on the compositions of foods and diets, another interesting possibility is that environmental factors might interact directly with human biology to influence the parameters of protein leverage. For example, any factor that reduces protein efficiency could exacerbate protein leverage, by increasing the intake target of the protein appetite, thus requiring a stronger compensatory response to protein dilution (Fig. 4.10) [47]. Such environment-induced variation in protein leverage might explain a number of poorly understood correlations between obesity and environmental factors. One example is the association of obesity with recent cultural transitions from traditional high-protein diets to Westernized diets rich in fats, oils, and simple carbohydrates [47]; another is and the vulnerability to later-life obesity of infants fed high-protein milk formulas [17]. In both cases, high-protein diets are hypothesized to developmentally program low-protein efficiency, thus exacerbating protein leverage (Fig. 4.10).

We cite these examples to illustrate how an understanding of the dynamics of human appetite systems might help to illuminate the factors that have driven the epidemic of obesity and associated disease in recent decades. The broader message, however, is that a nutritional ecology perspective, which emphasizes the interaction between biological traits and food environments, can provide a structured research framework for generating and testing hypotheses regarding the causes of health and disease in our radically altered industrialized food environments.

4.7 Conclusions

Statistics such as those with which we opened this chapter leave no doubt that nutrition science ought to be doing a better job of preventing premature deaths that are associated with malnutrition and chronic disease. The challenge, however, is to understand how the diverse and complex set of interacting causes drives the problem and to identify the key control points that are amenable to intervention to improve nutrition-related health. There is now widespread recognition that success will require a systems-based approach, which recognizes that relevant causal components are distributed across and between domains representing diverse academic disciplines and societal sectors [8–12, 83]. The

leadership, however, must come from nutrition science, which at present is ill-equipped for the task.

We have suggested in this chapter that a constructive branch for interdisciplinary engagement is with the basic biological sciences. Although nutrition science clearly has drawn heavily on chemistry, molecular biology, and physiology, its engagement with the core theory of biology – evolutionary and ecological theory – has been rudimentary. Such theory can provide a powerful framework for identifying pivotal systems components and interactions, and in this way direct and simplify the task, in much the same way that aerodynamics theory can help to direct aviation research. Ecology and evolution also provide a broad comparative perspective, which helps to identify patterns and generalities across a wide range of species and environments and, in this way, enrich the understanding of human-environment interactions. Nutritional ecology is the branch of the natural sciences that applies this approach in the context of nutrition.

As an example, we have shown how biological theory predicts that separate appetites would exist for particular nutrients and that these appetites would interact to broker beneficial outcomes across the range of varied food environments within which they evolved. We introduced nutritional geometry as an approach for investigating appetite interactions and examining how they are linked to broader aspects of human biology and industrialized food environments. Our analysis suggests, somewhat counter-intuitively, that the human propensity to overeat fats and carbohydrates is closely linked to our appetite for protein, via protein leverage. This, in turn, suggests a different focus for examining the causes of obesity, through drawing attention to the factors that influence dietary protein density. Our analysis also cautions against the common tendency to assume that if "too little is bad, a lot must be good," by highlighting the dangers both of diets with too low and too high protein energy density. It emphasizes the importance of dietary *balance*.

In closing, we emphasize that our main goal is not to suggest that we have solved the problem of energy overconsumption, obesity, and related diseases, but rather to introduce a biologically inspired approach that can help to structure nutrition research. Beyond the macronutrients and their different types and constituents, other dietary components such as fiber and micronutrients clearly are relevant to the problem, and likewise, many nutrient combinations are important for various other aspects of health. We suggest, however, that these relationships are best examined in a framework that is guided by biological theory and which examines the interactions among nutrients rather than considering them separately.

5.1 Background

Radial (rā′dē-əl)
radiates from or converges to a common center.
American Heritage Medical Dictionary, 2007

As the field of integrative and functional nutrition took root, a concrete model to help practitioners gain a deep understanding of this approach was needed. The ability to connect, synthesize, and apply information coherently using an integrated, whole systems-based lens to nutrition care led to the development of the Integrative and Functional Medical Nutrition Therapy (IFMNT) Radial [1]. Recent updates to the IFMNT Radial (referred to as the Radial) were based on emerging data on nutritional science, systems biology medicine, omics technologies, and the microbiome.

5.2 Overview

The Radial is a conceptual framework for critical thinking and clinical investigation that graphically depicts the multidimensional facets of a systems-based nutrition assessment in delivering medical nutrition therapy (MNT). The term medical nutrition therapy is defined as "nutritional diagnostic, therapy, and counseling services for the purpose of disease management, which are furnished by a registered dietitian or nutrition professional" [2]. The counseling component of MNT has been described as a "supportive process to set priorities, establish goals and create individualized action plans which acknowledge and foster responsibility for self-care" [3]. The circular architecture of the Radial depicts a person-centered process that allows for the evaluation of complex interactions and interrelationships. The Radial purposefully integrates the evidence-based Nutrition Care Process (NCP) for clinicians to apply an integrative and functional methodology to provide high-quality nutrition care. The radial is the core, five sphere, and four potential triggers.

The five primary spheres of influence in the Radial are as follows:

- Food, lifestyle, and environment
- Nutrition physical, signs, and systems
- Biomarkers
- Metabolic pathways and networks
- Systems (Fig. 5.1)

5.3 Core of the Radial: Personalized Nutrition Care

Personalized nutrition care highlighting the NCP is featured at the core of the Radial. It is centrally positioned and shows the four distinct, interrelated NCP steps including nutrition assessment, diagnosis, intervention, and monitoring/evaluation. Applying the NCP ensures that nutrition care is individualized and holistic using the highest quality information

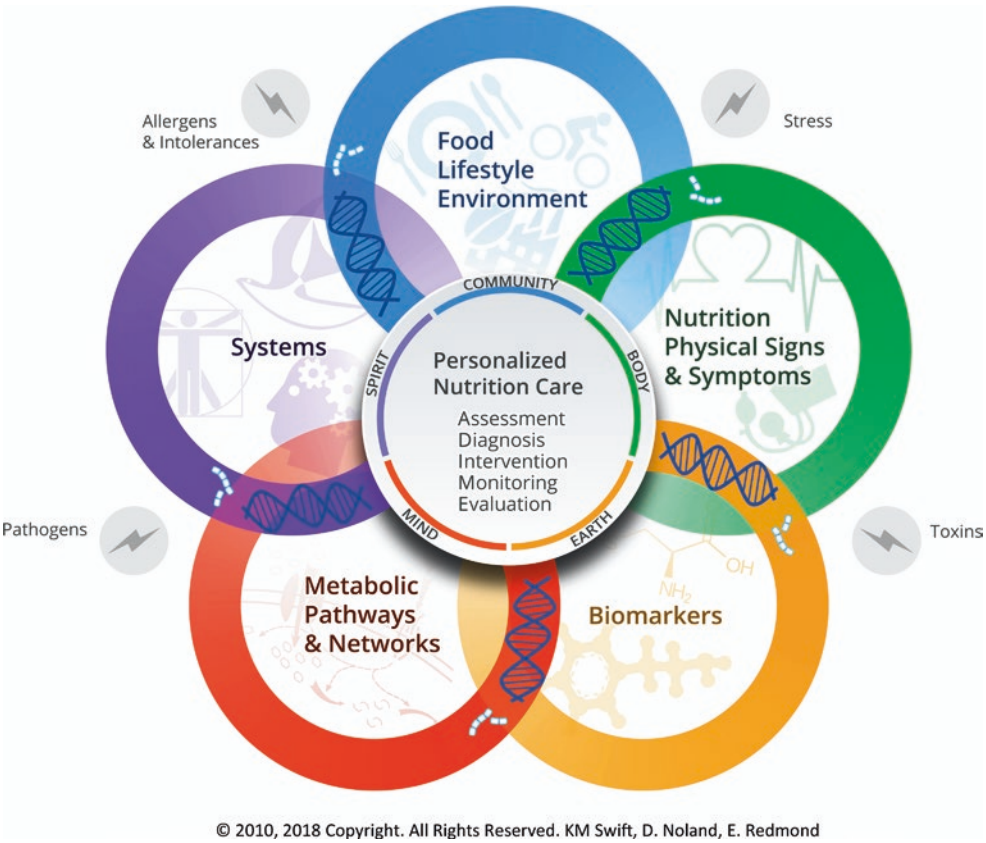

Fig. 5.1 The Radial. (Courtesy of Kathie Madonna Swift, Diana Noland, Elizabeth Redmond)

available to the clinician providing the service. A more detailed description of the NCP can be explored elsewhere [4].

A holistic approach to nutrition care embraces the assimilation of multiple components that influence one's well-being. Health is viewed as a dynamic quality where mind, body, and spirit are engaged in the fullness of life [5].

5.4 Mind, Body, Spirit, Community, and Earth

The Radial core illustrates the intermingling of mind, body, spirit, community, and earth and its association with personalized nutrition care, since all of these factors influence one's health and healing. Mind, body, and spirit are viewed as wholeness versus distinct and separate physiological, psychological, and spiritual units. The value of community and social networks as a component of health and wellness must be considered since social contexts influence biological systems [6]. An appreciation of our intimate connection to the earth and the healing power of nature to foster one's health is also valued as an integrative concept of food and sustainable nutrition.

5.5 DNA Strands and Microbes

The sequencing of the human genome and growing knowledge regarding genetic variation and biotechnological omics advances is contributing to the development of personalized nutrition. The Radial depicts genetic influence by the strands of DNA that surround the core. Personalized nutrition is an application of nutritional genomics and seeks to enhance health through the understanding of "the functional interaction between bioactive food components with the genome at the molecular, cellular, and systemic level in order to understand the role of nutrients in gene expression and… how diet can be used to prevent or treat disease" [7]. Diversity in the genetic profile among individuals impacts nutrient requirements, metabolism, and response to dietary, nutritional, and lifestyle interventions [8].

The microbiome revolution has established that microbial signatures vary between individuals far more than genetics [9]. Dietary habits and lifestyle affect the gut microbiota composition in dramatic ways. This vital influence must be taken into account and is represented by the microbes in the graphic that, like the DNA strands, radiate to all five spheres of the Radial. The composition of the microbiome and its diverse activities are involved in most, if not all, of the biological processes, and thus, it is a key player in health and disease at all stages of the life cycle [9].

The concept of "food as information" influencing genetic expression, manipulating the microbiome and, consequently, supporting or hijacking the patient's physiological systems is cardinal to the integrative and functional model. The Systems sphere radiates from the core of the Radial and underscores the imbalances that are created by poor diet, unhealthy lifestyle behaviors, and environmental exposures such as chronic inflammation, oxidative stress, digestive and detoxification disturbances, metabolic chaos, neuro-endocrine-immune disruption, and nutritional depletion.

5.6 Food, Environment, and Lifestyle

Food is the ideal starting point in an IFMNT assessment since it is a powerful determining factor in health and disease. Hippocrates is credited with the "food as medicine" philosophy, although scholars debate the origin of this theme since nutrition has been a central premise in ancient, traditional forms of medicine [9, 10]. A modern, integrated concept of food as medicine emphasizes scientific understanding of nutrition with lifestyle behaviors in relation to a person's ability to realize vital goals of healthy living. Food is valued as an instrument for vibrant health and an essential tool to kindle healing by restoring nutritional integrity.

Changes in the human diet and food systems have altered crucial nutritional attributes that impact biological systems including glycemic and insulinogenic load, carbohydrate quality, fiber content, fatty acid composition, macronutrient balance, micronutrient density, phytonutrient richness, sodium-potassium ratio, and acid-base balance [11]. A theme of healthful eating that considers these nutritional factors has been described with the strength of evidence supporting a plant-based diet with foods close to nature [12]. Other elements of diverse diets and healthy dietary patterns include limited refined starches, added sugars including fructose, avoidance of ultra-processed foods, and limited intake of certain fats.

Personalized nutrition extends beyond these general principles of healthy eating and targets the underlying root causes of system imbalances, is specific to the individual's unique nutrient requirements, and is designed with biological compatibility and lifestyle in mind [13]. It seeks to understand how diet and lifestyle-related modulators act together and coconspire to create the perfect storm of complex, chronic disease. For example, personalized nutrition recognizes that following general nutrition guidelines may result in high glycemic responses in some individuals, accelerating metabolic decline and that there can be unique dietary responses because of biochemical uniqueness. Thus, consideration of personal variables including sex, age, genetics, biomarkers, lifestyle, and environmental factors must be taken into account in tailoring a personalized nutrition prescription [14]. Food intolerances such as gluten, fructose, FODMAPs, food chemicals, and histamine are other examples of the dietary discord that can impact the health of some individuals while not affecting others. The age-old saying, "one person's meat is another person's poison," is now viewed in light of the scientific revelation that the multi-tasking, metabolically active microbes play a significant role in the unique interpretation by the body of food as friend or foe [15].

To be effective, personalized nutrition care must integrate the scientific approach with cultural, emotional, ethical, spiritual, social, and sensual understandings of food [16]. The

science of nutrition and the *art* of dietary behavior change are indispensable partners in personalized nutrition care that is relational in nature. The heart of nutrition assessment lies in a therapeutic relationship that values the patient's story (see ▶ Chap. 39). This means that the nutrition professional is able to listen reflectively to the patient's narrative, absorb what the person is sharing, and understand their concerns. It must go beyond root-cause analysis of medical history, anthropometrics, symptomatology, testing, and other metrics and focus on the patient's humanity and their desire to shape their well-being. This requires skills and competencies in addressing health behaviors and engaging the patient in self-care management of mind, body, and spirit. It implies attention of the patient on their personal health goals, increased self-awareness, and commitment on ways to achieve and maintain optimal health. Shared decision-making by both the clinician and patient is essential in the design of a nutrition intervention plan that is truly personalized, actionable, practical, sustainable, and, ultimately, successful.

Integrative health questionnaires can assist the clinician in the personalized nutrition care process. Supportive tools include food records, activity journals, circadian patterns, timeline of significant medical events, medication and dietary supplement lists, symptom appraisal forms, nutrition-focused physical findings, and biomarker results from both conventional and functional laboratory testing. Individual health risks of diet, physical activity, substance abuse, excess stress, sleep deprivation, environmental toxins, pathogens, food allergens, and intolerances must also be unearthed. Open-ended questions can reveal aspects of the patient's story that may not have been revealed in specific data collection tools and techniques. These questions can help the clinician and patient as co-investigators in uncovering unique and deeply personal themes that affect an individual's health:

- *Did something trigger a change in your health?*
- *What makes you feel better?*
- *What makes you feel worse?*
- *Have you made any changes in your eating habits or lifestyle because of your health?*
- *What do you think would make the most difference in your health and well-being?*
- *In your own words, tell me your story…*

The personalized nutrition care process, when delivered skillfully, engages the patient in self-care to attain their highest health potential. A thorough understanding of how the trilogy of food, environment, and lifestyle impact physiological systems must be realized for the clinician to apply this in practice and support the patient with a truly personalized care plan.

5.7 Nutrition Physical Exam and Signs and Symptoms

Most patient encounters begin by hearing the patient's story with appropriate history taking, identifying the signs and symptoms with which they are presenting, and the nutrition physical exam (NPE). Universally, basic anthropometrics are measured: blood pressure, height, weight, and calculating BMI. For the IFMNT approach, the NPE can be expanded with tools that add more detailed information for assessing the nutritional and body composition status. These tool options to consider collecting nutrition data are:

- Tape measure: measures waist circumference
- Bioelectric impedance analysis (BIA) (full body): measures several parameters described in ▶ Chap. 22 on Body Composition. One of the measurements most commonly appreciated is percentage of body fat/lean mass and BMI.
- Fingertip Pulse Oximeter Blood Oxygen Saturation Monitor: measures oxygen saturation and pulse rate
- Oral/axillary thermometer: measures body temperature
- Calipers: measures body fat

Signs and symptoms can be documented by patient questionnaires completed prior to the client visit, or upon arrival at the appointment. The medical symptoms questionnaire (MSQ) commonly used in integrative and functional medicine practice measures symptoms based on systems biology, according to body systems. The practitioner's assessment of the questionnaire can be done quickly to easily see where the system priorities are to consider for diagnosis and intervention for the client. The systems and related symptoms often included on the questionnaire are:

- *HEAD*: headache, faintness, dizziness, insomnia
- *EYES*: Watery or itchy eyes; swollen, reddened/sticky eyelids; bags, dark circles; blurred or tunnel vision (does not include near or far-sightedness)
- *EARS*: Itchy ears; earaches, ear infections; drainage from ear; ringing/hearing loss
- *NOSE*: Stuffy nose, sinus problems, hay fever, sneezing attacks, excessive mucus
- *MOUTH/THROAT*: Chronic coughing; gagging/throat clearing; sore throat, hoarseness; swollen/discolored tongue, gums, lips; canker sores
- *HEART*: Irregular/skipped beats, rapid/pounding beats, chest pain
- *SKIN*: Acne; hives, rashes, dry skin; hair loss; flushing, hot flashes; excessive sweating
- *LUNGS*: Chest congestion; asthma, bronchitis; shortness of breath; difficulty breathing
- *DIGESTIVE TRACT*: Nausea, vomiting; diarrhea; constipation; bloated feeling; belching, passing gas; heartburn; intestinal/stomach pain
- *JOINTS/MUSCLE*: Pain or aches in joints, arthritis, stiffness/limited movement, pain or aches in muscles, feeling of weakness or tiredness
- *WEIGHT*: Binge eating/drinking, craving certain foods, excessive weight, compulsive eating, water retention, underweight
- *ENERGY/ACTIVITY*: Fatigue/sluggishness; apathy, lethargy; hyperactivity; restless leg; jetlag
- *MIND*: Poor memory; confusion, poor comprehension; poor concentration; poor physical coordination;

difficulty making decisions; stuttering or stammering; slurred speech; learning disabilities
- *EMOTIONS*: Mood swings; anxiety, fear, nervousness; anger, irritability, aggressiveness; depression
- *OTHER*: Frequent illness; frequent or urgent urination; genital itch or discharge; bone pain
- *PAST SURGERIES AND DATES*: See ▶ Chap. 56 for a sample questionnaire.

5.8 Biomarkers

Nutrition-related biomarkers are biological indicators. While a nutrition assessment is essential to assess what nutrients the diet is providing, an evaluation of biomarkers may provide a more detailed picture of what the client is actually digesting, absorbing, and utilizing. Diet assessments may not always coordinate with laboratory values of individual nutrients. This may be due to many factors, such as an individual having a greater need for a nutrient than the RDA, poor-quality food or supplements, a genetic variation, impaired absorption, exposure to a specific toxin whose detoxification requires specific nutrients, etc.

5.9 Laboratory Testing

Most clinicians are familiar with conventional laboratory testing of standard markers. In addition to conventional lab testing, integrative and functional clinicians also often utilize specialty diagnostic laboratories, which are often early adopters of new testing. Functional medicine was an early adopter of the concept of utilizing organic acid measurements for assessment of biochemical pathways and metabolomics. Functional medicine clinicians also incorporate a systems-based interpretation of standard laboratory tests.

There are two primary types of laboratory tests: indirect (also referred to as functional) or direct.

A functional test is an evaluation of an analyte that is dependent on the marker. For example, levels of methylmalonic acid (MMA) measure functional need for vitamin B12. Vitamin B12 is a nutrient cofactor needed for the enzyme methylmalonyl-CoA mutase. It breaks down L-methylmalonyl-CoA to succinyl-CoA, which then goes into the Krebs cycle. If vitamin B12 is not available in adequate amounts, the pathway will stall and MMA will build up. Thus, elevated MMA levels in both urine and blood have been correlated to vitamin B12 deficiency [17].

Direct laboratory testing identifies levels that are actually there, such as serum 25-hydroxy vitamin D. Though there has been significant disagreement on the "ideal" vitamin D level, as the level needed for an individual may vary significantly, there is strong consensus on the specimen selection of serum 25-hydroxy vitamin D.

Specimen selection should generally be based on what literature has identified. For example, urine amino acids can identify what a person has eaten over the last few days, while serum amino acids can tell more about overall amino acid status. Additionally, whole blood lead may not be the best way to assess lead levels, but it is the way public health organization and researchers check lead levels, and thus if you are evaluating lead levels, it is best to check whole blood lead so comparisons can be made.

Beyond specimen selection, clinicians should be aware of reference ranges and how they are set. While some biomarkers have medical decision points identifying what each level means, such as levels of A1C, other markers do not have a standard accepted reference range or decision point. For many markers, the reference range is represented by what has been noted within a "normal" population. A patient is considered abnormal if they are more than 2 standard deviations (>95.4%) from the mean within the population utilized to set the reference range. Researchers may correlate values with disease status, but if comparisons are made to research studies, the laboratory technique and reference range population must be compared. For example, elevated alpha-hydroxybutyrate has been associated with insulin resistance, but the specific level is not established.

Integrative and functional clinicians look at several areas of laboratory assessments, including metabolism, inflammation and immune reactions, nutrition, nutrigenomics, digestion and absorption, biotransformation, etc.

Metabolism: Metabolism includes energy metabolism and metabolomics. Metabolomics accesses metabolite profiles to detect which biomarkers or biomarker patterns are associated with a disease in the hope of better defining a specific metabolic profile for each condition or disease. It has also been referred to as the specific metabolic "fingerprint" that is unique to each person and disease. In other words, metabolomics takes into account the impact of lifestyle factors like diet, movement, and the environment to illustrate overall health.

Inflammation: Evaluation of inflammation can identify systemic inflammation, such as hsCRP, or it can be site-specific, such as fecal calprotectin to evaluate gastrointestinal inflammation. Different specimen types can identify the type of inflammation, lipid peroxides identify fatty acid membrane oxidation, and 8-hydroxy-2-deoxyguanosine evaluates oxidative damage to DNA. Oxidative stress and inflammation are key markers of nutrient deficiencies [18]. Nutrients are the substrates for many immune reactions, such as fatty acids and immune cytokines. Nutrients can also modulate the immune system, for example, antioxidants tempering immune responses to inflammation. While classic inflammation is short term, chronic "metaflammation" is a low-level long-term inflammation that is associated with inflammation-related diseases. Chronic inflammation differs because there is only a small rise in immune markers (i.e., a four- to sixfold increase versus a several hundred-fold increase seen in acute reactions) which can lead to systemic effects and is associated with a reduced metabolic rate [19].

Testing can also identify the immune system's reaction to components in foods, such as proteins, toxins, and other bioactive components. Functional medicine evaluates a patient's

Table 5.1 Micronutrient laboratory assessment

Minerals	IOM assessment [22–24]	Possible functional or other testing options
Magnesium	A serum magnesium concentration of less than 0.75 mmol/liter (1.8 mg/dl) is thought to indicate magnesium depletion.	Serum/plasma magnesium concentration, red blood cell (RBC) magnesium concentration, and urinary magnesium excretion appear to be useful biomarkers of magnesium status in the general population [25].
Zinc	Factorial analysis was used to set the Estimated Average Requirement (EAR).	Physical growth response to zinc supplementation [24]. While both plasma and serum zinc concentrations are used as indicators of zinc status, plasma zinc concentration is preferable because of the lack of contamination of zinc from the erythrocyte [26].
Copper	The primary criterion used to estimate the EAR for copper is a combination of indicators, including plasma copper and ceruloplasmin concentrations, erythrocyte superoxide dismutase activity, and platelet copper concentration in controlled human depletion/repletion studies.	Low serum copper. Serum copper and ceruloplasmin levels may fall 30% in deficiency [27]. An elevated homovanillate/vanilmandelate has been reported to identify copper need since the conversion of dihydroxyphenylalanine (DOPA) to epinephrine requires copper, though research is limited. Homovanillate is the breakdown product of DOPA and vanilmandelate is the breakdown product of epinephrine and nor-epinephrine. The ratio has been used as a screening for Menkes [28].
Vitamins	**IOM assessment**	**Possible functional or other testing options**
Vitamin K	Due to insufficient laboratory values to estimate levels, an Adequate Intake (AI) was set based on representative dietary intake data from healthy individuals.	A direct measure of vitamin K is not of value as both serum and plasma phylloquinone reflect recent intakes (24 hours) and do not responds to changes in dietary intake [24]. Carboxylated Gla (Gla) or undercarboxylated osteocalcin (uc-OC) may be used. A deficiency of vitamin K upregulates the level of serum undercarboxylated osteocalcin (ucOC), and serum ucOC has been found to correlate with fracture risk [29].
Folate	The primary indicator used to estimate the RDA for folate is erythrocyte (RBC) folate in conjunction with plasma homocysteine and folate concentrations.	Serum folate, without a concurrent vitamin B12 deficiency, is a useful biomarker for folate deficiency [30]. Formiminoglutamic acid (FIGLU) is an intermediate metabolite in L-histidine catabolism in the conversion of L-histidine to L-glutamic acid. It may be an indicator of vitamin B12, folic acid deficiency, or liver disease [31]. Measurement of urinary FIGLU excretion after a histidine load has been used as a marker of folate in those with adequate B12 levels [32].
B3 Niacin	The most reliable and sensitive measures of niacin status, also used to set the RDA, was urinary excretion of the two major methylated metabolites, N1-methyl-nicotinamide and its 2-pyridone derivative (N1-methyl-2-pyridone-5-carboxamide).	An increase in urinary excretion of kynurenic acid and a decreased in quinolinic acid were found in pellagra that was corrected with niacin supplementation [33]. Urinary branched chain keto acids (organic acids) positively identified subjects with B vitamin-complex deficiency; those with the highest level of urine branched chain amino acids (BCAA) were more likely to be B vitamin deficiency [34].

reaction to foods or environment. By definition, IgE reactions are true allergic reactions, while other reactions are food intolerances or sensitivities, measured with immunoglobulins (IgG) or white cells, and have significantly less literature support. IgG testing (ELISA) includes IgG1, IgG2, IgG3, and IgG4. IgG testing is controversial, as limited evidence from peer-reviewed research has found correlations with migraines and IBS [20]. Some researchers believe IgG is identifying exposure, since "healthy" people can have elevated levels. Leukocyte testing includes both the mediator release and the leucocyte activation test. Though both evaluate changes in white blood cells, they are different processes. Both are also controversial with limited peer-reviewed literature, though, like IgG, many clinicians claim to find them helpful in clinical practice [21].

Nutrition: As noted, personalized nutrition is specific to the individual's unique nutrient requirements. Table 5.1 identifies examples of both laboratory markers used by the IOM in setting recommended levels, and functional or other testing options. Though there is often controversy with the specific tests selected by the IOM, it is important to know the technique and specimen used, and how other testing options compare to it.

- Micronutrients are common enzyme cofactors. Identifying inadequate levels of individual micronutrients may also identify possible blocks in biochemical pathways (Table 5.2).

Nutrigenomics: Nutrigenomics is the study of the interaction of nutrition and genes and has been shown to personalize

Table 5.2 Functional nutrition approach to macronutrients

Protein	Functional assessment goes beyond total protein evaluation and identifies individual amino acids and types of protein (plant or animal). Plasma assessment of individual amino acids helps to identify overall level of protein intake and processing. Plasma identifies longer term status and use. Urine identifies intake in the last 24 hours and some metabolic issues. Both plasma and urine assessments are best done in a stable dietary intake. Blood amino acids can be measured with a blood draw or from a finger stick.
Fat	Functional assessment goes beyond evaluating standard blood lipids such as TAG, LDL, and HDL and includes individual fatty acids, such as the polyunsaturated fats omega-3 and omega-6, as well as monounsaturated fats and saturated fats. Specimen types include whole blood, plasma, or RBC and are available in blood draw or finger stick. Fatty acids are measured as a percentage of total or as a concentration, and direct comparisons should not be made. Further, the different methods of expressing fatty acids can lead to dissimilar correlations between blood lipids and certain fatty acids [35]. Evaluation of fatty acids of varying carbon chain length and degree of saturation can help to identify dietary intake and have been noted as biomarkers of various conditions. A review of individual fatty acids helps to evaluate function of desaturase and elongase enzymes, which can impact treatment. For example, the conversion of alpha-linolenic acid (ALA) to eicosapentaenoic acid (EPA) is not always efficient and supplementation with flax, high in ALA, may not result in expected increases in EPA. Testing would aid in identifying those who are not making the conversion.
Carbohydrates	Conventional assessment of carbohydrates is generally the assessment of the body's blood sugar response and includes glucose and A1c. Functional medicine also evaluates additional early markers of biochemical disruption using metabolomics, such as identifying alpha-hydroxybutyrate or impaired plasma levels of branched-chain amino acids, which may identify risk of T2D and CVD [36]. The composition of the microbiome can also identify the impact of carbohydrate and fiber intake. Plant-focused diets high in fiber are associated with greater microbial diversity and higher levels of *Prevotella* over *Bacteroides*. Low levels of SCFAs (acetate, propionate, butyrate) in stool can identify poor carbohydrate (fiber) intake or inadequate gut bacterial function [37]. Additionally, high-protein diets can increase the level of bacterial products of protein breakdown, including the short-chain proteolytic fatty acids, valerate, iso-butyrate, and iso-valerate [38, 39].

For comparison, the IOM Recommended Dietary Intake (RDI) for macronutrients in adults is 45–65% of their calories from carbohydrates, 20–35% from fat, and 10–35% from protein [40]

treatment. Test profiles are often buccal swabs and packaged to evaluate a specific area such as weight loss, immune function, nutrient absorption, etc. Previously, the US Food and Drug Administration raised concerns about the validity of the information and the potential for inappropriate medical actions, highlighting the need for practitioners to be aware of the literature of individual single nucleotide polymorphisms (SNPs) [41].

Digestion and Absorption: Functional assessment of digestion and absorption includes tests related to the gastrointestinal tract and its function. Assessment of a patient's digestion and absorption can be assessed in a variety of tests. Two examples are pancreatic elastase 1 (PE1) and fecal fats. PE1 is a proteolytic enzyme that identifies the function of the exocrine pancreas (not to be confused with the endocrine pancreas). The exocrine pancreas produces 3 types of enzymes: amylase, protease, lipase. If it is impaired, digestion may be impaired. Exocrine pancreatic insufficiency is identified with an elastase level < 200 μg/g stool [42]. Fecal fats are used to evaluate fat malabsorption. The gold standard for fat malabsorption is a 3-day quantitative determination of fecal fat. It is cumbersome and takes significant dietary preparation, so a single fecal assessment is often done as an initial evaluation [43].

Assessment of gut bacteria or the microbiome can aid clinicians understanding of the impact of individual bacteria and overall diversity. Assessment is generally done with fecal samples, though breath tests can also identify levels of some gut bacteria. The microbiome is a primary player in the immune system and is heavily impacted by diet, lifestyle, and environment. There are many culture-independent techniques in use, such as fluorescent in situ hybridization (FISH), polymerase chain reaction (PCR), next- and third-generation sequencing, etc. While each technique is valid, the results are not comparable. Even laboratories that do the same stated process such as PCR assessment are generally not comparable due to a lack of standardization. Evaluation of microbiome levels with disease associations or conditions needs to be done using comparable testing.

Intestinal permeability is another concern that functional clinicians evaluate in a full assessment. The intestine is lined with a single layer of epithelial cells held together with tight junctions (TJ), which coordinate exchange between lumen and tissues. Disruption of the intestinal barrier impairs function and may increase the risk of specific disease. Zonulin is a physiologic modulator of intercellular intestinal tight junctions. An increase in zonulin has been proposed to identify a "leaky gut" and has been related to autoimmune disease, metabolic disorders, heart disease, and intestinal disease such as IBS, IBD, and non-celiac gluten [44, 45]. Unfortunately, zonulin has been difficult to test accurately in commercially available tests [46].

Detoxification (also known as biotransformation): Biotransformation refers to the process of transforming tox-

ins, hormones, etc. through the phases of detoxification. Functional clinicians can support the process by ensuring adequate nutritional status of detoxification pathways and identifying toxin levels when needed. There is no single test to evaluate detoxification phases. Phase I is generally done with genetic SNP testing and phase II includes status of amino acid substrates and nutrient co-factors. Detoxification is heavily reliant on enzymes, such as cytochrome P450 oxidase enzymes (CYP450) and nutrient status. Diet can significantly impact the ability to detoxify because it provides both needed nutrients and is a leading contributor of body toxins. Testing for the presence of toxins is available from several laboratories. The ability to compare toxin levels to population data, such as NHANES, allows clinicians to compare client's levels to the general population.

5.10 Metabolic Pathways and Networks

Understanding biochemical pathways and how they function is essential in functional medicine. Biomarkers are not just levels of individual analytes; they include markers of status and pathway function. Individual nutrients often work as nutrient cofactors, and can impact the ability of a pathway to flow smoothly. In order to fully evaluate a patient's biochemical status, clinicians must know the key pathways and networks, such as methylation, conjugation, nutrient breakdown, urea cycle, etc., including substrates, products, enzymes, and cofactors. After a full evaluation of a patient's history, signs and symptoms, anthropometrics, diet assessment, and laboratory evaluations, clinicians can take the next step of identifying key pathways that could be impaired. Several examples are listed below, including vitamin B12 and MMA, and breakdown of fatty acids and BCAA.

Vitamin B12 and Methylmalonic Acid (MMA): When MMA levels are elevated, it may identify a need for vitamin B12 due to inadequate intake or increased need. If diet assessment identifies an adequate intake, there may be increased needs due to other factors, such as decreased stomach acid or increased methylation issues. As seen in the simplified diagram below, L-methylmalonyl-CoA (substrate) is converted to succinyl-CoA (product) via the enzyme methylmalonyl-CoA mutase. The enzyme requires a nutrient-cofactor, adenosylcobalamin (vitamin B12). If the enzyme function is decreased, the L-methylmalonyl-CoA will build up and be excreted as MMA. The enzyme may have decreased function due to a genetic SNP or decreased levels of its nutrient cofactor, vitamin B12. As with most pathways, it is important to know that there are additional related pathways that can also be impacted. For example, converting homocysteine to methionine (methylation) may also be increased with a need for B12 (Fig. 5.2).

Fatty Acid Breakdown Eicosanoids are signaling molecules that result in a range of processes generally related to immune and inflammation. They are derived from omega-3 and omega-6 fatty acids, as seen in Fig. 5.2. Diet provides the fatty acids and nutrients support the breakdown pathways.

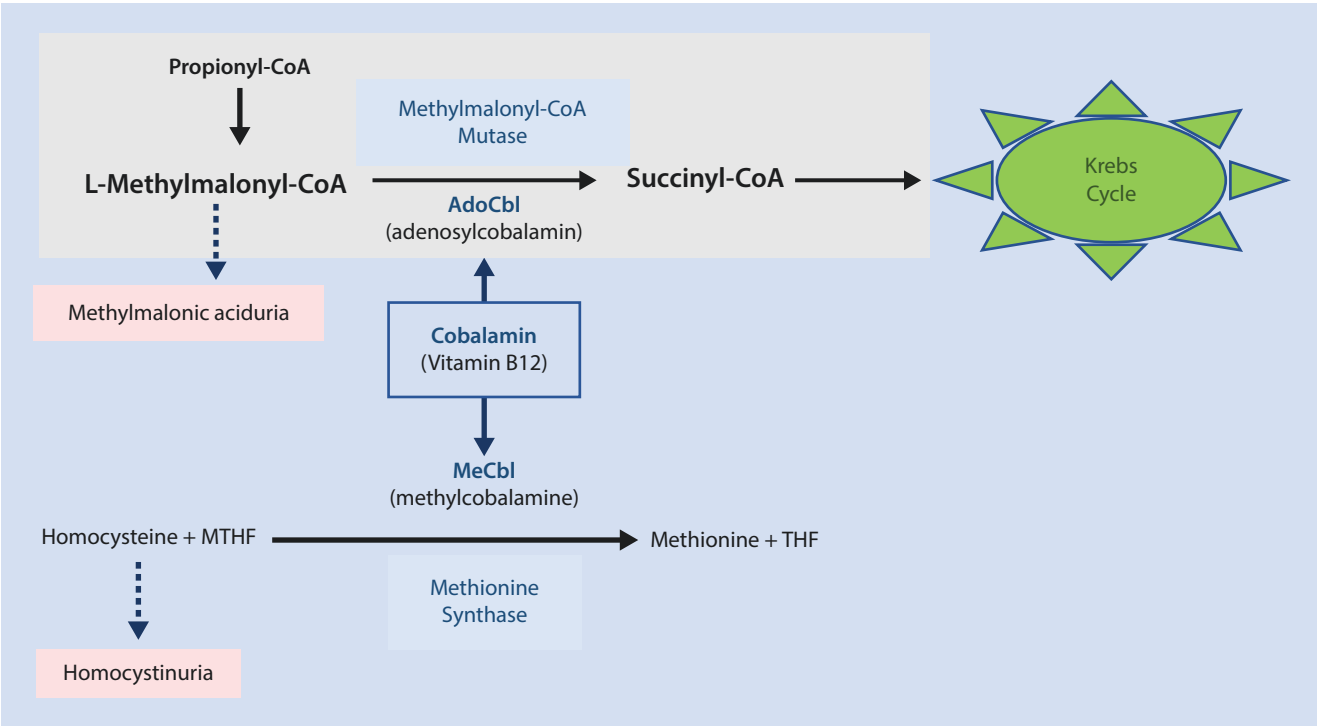

Fig. 5.2 Methylmalonic acid (MMA) pathway. (Courtesy of E. Redmond, PhD, RDN)

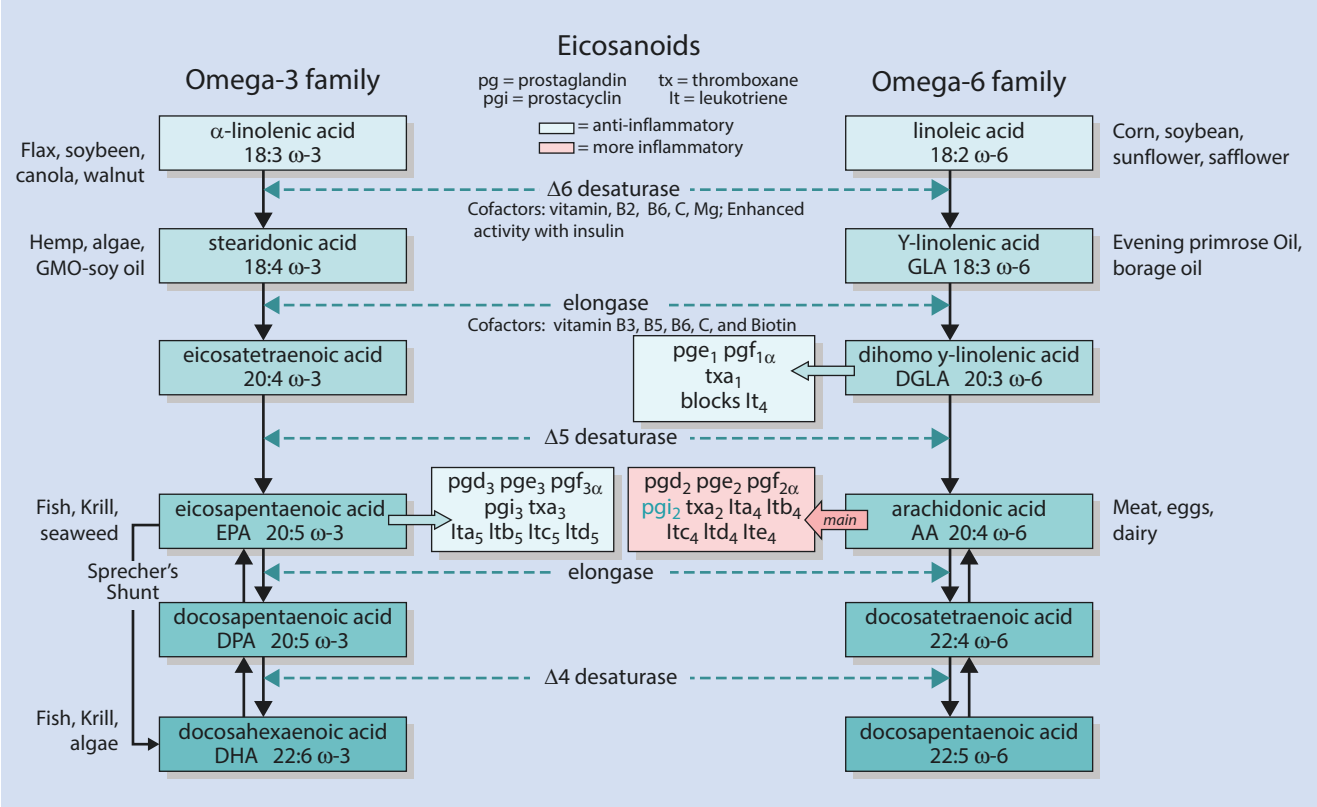

Fig. 5.3 Eicosanoid pathway [47]. (Adapted with permission from: ▶ https://commons.wikimedia.org/wiki/File:EFA_to_Eicosanoids.svg)

Altered fatty acids have been associated with several metabolic diseases, including diabetes, metabolic syndrome, hypertension, alcohol, radiation exposure, and others. The eicosanoid pathway is heavily reliant on elongase and desaturase enzymes, which are dependent on adequate nutrient cofactors. Though a conclusive list has not been developed the following are thought to play a role in desaturase and elongase enzyme function, vitamins B2, B3, B5, B6, C, and biotin, and minerals zinc and magnesium. Additionally insulin is believed to impact function [48–50] (Fig. 5.3).

Furthermore, evaluations of specific monounsaturated and saturated fatty acids can also identify functional impairments. The Δ9-desaturase enzyme or stearoyl-CoA desaturase (SCD) catalyzes the synthesis of monounsaturated fatty acids, primarily oleate (18:1) and palmitoleate (16:1), from saturated fatty acids, palmitate (16:0), and stearate (18:0). Stearic acid is correlated to cholesterol level and Δ9 may be impacted by insulin; thus, an evaluation may help to identify early biochemical function and possible increased risk [51, 52]. A decrease in insulin activity reduces the activity of desaturase enzymes that convert saturated to monounsaturated fats, which can be identified by increases in blood saturated fat levels.

Branched-chain Amino Acids (BCAA) Breakdown: Leucine, isoleucine, and valine are BCAAs. The BCAAs differ from other essential amino acids in that the liver lacks the enzymes to break them down or catabolize them. They are broken down to their keto-acids with transaminase enzymes and the nutrient cofactor vitamin B6. If vitamin B6 is not in adequate supplies, the BCAA amino acids may build up. The next step utilizes a dehydrogenase enzyme and its required nutrient cofactors, vitamins B1, B2, B3, B5, and lipoic acid (LA), which then flow into the Krebs cycle in the mitochondria. Identification of elevated keto-acids may signal a need for B-complex vitamins [34]. Thus, an impairment in the BCAA process has been proposed to impair basic mitochondrial function. Research has found that levels of BCAAs were higher in some individuals with obesity and have been associated with worse metabolic health and future insulin resistance or type 2 diabetes mellitus (T2DM). Insulin resistance may increase protein degradation since insulin normally suppresses it. In clients with metabolic issues, functional clinicians may evaluate plasma BCAAs as well as their keto acids to identify issues in the pathways (Fig. 5.4 and Table 5.3).

The evaluation of pathways and metabolites is continuously being researched. Key resources include the following

5

Table 5.3 Branched-chain amino acids (BCAA)

BCAA)	Enzyme plus cofactors	BCAA keto-acid	Enzyme plus cofactors
Valine	*BCAA transaminase + vitamin B6*	Alpha-ketoisovalerate	*Branched-chain keto-acid dehydrogenase + B1, B2, B3, B5, LA*
Leucine		Alpha-ketoisocaproate	
Isoleucine		Alpha-keto-beta-methylvalerate	

5.11 Systems

The foundation of integrative and functional medicine is systems biology [53]. There is a broad consensus as to the definition of systems biology. The biological systems described in IFMNT recognize that the whole human organism is comprised of systems working together contributing to total function. The systems included in assessment of the whole patient story are those where disease can be promoted with the individual's identified pathophysiological symptoms and imbalances. In systems biology, of three primary principles, the first is *diversity*, where there is the appreciation of the complex molecular and genetic uniqueness of each individual. The depth of grasping uniqueness has been enhanced with the discovery and identification of the human genome.

The second key characteristic of systems biology is the recognition of the *complexity* of biological systems and the perturbations of those systems that can promote disease. In contrast to the reductionist medical acute-care model of quickly finding the diagnosis and applying a standard of care, a systems biology-based medicine and medical nutrition therapy applies a whole-systems approach to identification of "root causes" that is a better fit to treatment of chronic diseases.

Thirdly, *simplicity* reflects the application of systems biology to manage the complexity of metabolism to create manageable healthcare procedures that can be applied clinically. Simplicity refers to prioritizing the systems that most impact the individual. Once systems of concern are ranked in importance, they enable a realistic analysis of "root" causes of a chronic disease condition. Prioritizing and simplifying systems that need modulation increases the possibility of successful outcomes for such patients. Prioritized systems require practitioner skills in modulating the systems' biochemical networks, especially in the use of nutrients as cofactors and structural components. This knowledge is foundational for simplifying the development of effective interventions addressing "root causes" with food, dietary supplementation, and lifestyle education. This knowledge depends on the principle that one disease can have multiple influences, with nutrient cofactors being primary when searching for "root causes."

Chronic diseases are diet- and lifestyle-related with the influence of an individual's unique genotype. Thirty years ago, the Institute for Functional Medicine (IFM) was the first to provide a framework, "The IFM Matrix," for how to harness the complexity of chronic diseases into a manageable

clinical tool that simplifies primary priorities needing metabolic correction (see ▶ Chaps. 7 and 47). Later, IFMNT practitioners implemented the conceptual diagram, The Radial (see ◘ Fig. 5.1), to target the nutrition component in the practice of patient care. For a systems biology approach to be effective, the uniqueness of each individual becomes "patient-centered care" [54], using tools like the Radial to "extract simplicity out of chaos" [53].

Working knowledge of the following systems equips the IFMNT practitioner with advanced skills in "metabolic correction" once an imbalance is identified (see ▶ Chap. 7).

As we review the systems below, it is obvious that there is interaction among all the systems to produce a personalized phenotype, but at any time, there are usually two or three of the systems raising a flag indicating dysfunction and needing restoration back to wellness.

5.12 Gastrointestinal System

» All disease starts in the gut. –Hippocrates

The gastrointestinal tract provides the largest interaction of the human with the environment primarily through ingested food, water, and beneficial fermented bacteria to promote a healthy gut ecology. The gut houses more than 70% of the immune system in its lymphoid tissues. It is also the secretor of many neurotransmitters and other life-giving metabolites like the short-chain fatty acid butyric acid, the primary repair fuel for colonocytes (colon cells), which promotes increased energy and cell proliferation and may protect against colon cancer. Key GI tract interventions are based on a whole foods low-antigen diet, with adequate prebiotics of soluble fiber and fermented foods or supplemental probiotics. A common thoughtful functional medicine approach to gut restoration is the 5R program [55]. It begins with *removing* the offender – whatever is in excess or an antigen for an individual; then *replacing* digestive secretions/enzymatic activity and fiber if indicated, repletion of insufficient or deficient nutrients; next, *reinoculating* to restore the balance of good bacteria, pre- and probiotics, adequate hydration; *repairing* the gut barrier that may be compromised from long-standing insults like antibiotics, antigen exposure, toxins, and emotional conflicts; and finally *rebalancing*. This type of protocol provides a significant tool to provide treatment for an individual who is experiencing gastrointestinal distress [56].

5.13 Immune System: Defense and Repair

With chronic systemic inflammation being a common denominator with all chronic diseases, it is important to focus on the condition of a person's immune system. This system, when perturbed, responds with inflammation that can lead to recoverable illness like flu and autoimmunity, as well as life-threatening cancer. The IFMNT practitioner can assess if the immune system is a priority for an individual by using the tools of nutrition physical exam, laboratory biomarkers of inflammation like C-reactive-protein-high sensitivity, sedimentation rate, differential with hearing the patient's history, and diagnosis/symptoms. Dietary history can reveal a diet of pro-inflammatory character that can be modulated to improve the immune response for the individual. Recent recognition of genomic polymorphisms that may increase risk of inflammation includes people with HLA DQ2 and DQ8 who have increased predisposition to celiac disease-related inflammation (see ▶ Chap. 49 Autoimmune).

5.14 Cardiovascular System: Cardiometabolic Comorbidities

According to the World Health Organization, heart and cardiovascular diseases are the most common chronic diseases worldwide. The bigger picture is the pathophysiology of the cardiometabolic system that underlays the trend toward the high risk of cardio diseases for an individual.

Inflammation is foundational to the early stage development of atherosclerosis, along with contributing chronic infections, pro-inflammatory dietary choices, poor sleep, endocrine-disrupting chemical toxins, etc. Nutritional and lifestyle interventions provide powerful change agents to modulate the cardiovascular system.

5.15 Endocrine System: Hormonal Health Influences

The endocrine system's response to our environment to message cellular activity is important to consider when assessing a patient. Two glands in jeopardy today are the adrenal and pancreatic glands. The adrenal gland responds to stress and lack of quality sleep-producing cortisol (stimulatory) elevations. The concerns for the hormones produced by the pancreas are the influence of insulin which, when in excess, is involved in promoting sarcopenic obesity (loss of muscle, gain of body fat) and metabolic syndrome. The pancreas also has an important influence by secretion of the digestive enzymes: lipases, amylases, and proteases to digest the dietary intake of the macronutrients fat, carbohydrate, and proteins. Other important glandular systems are thyroid, parathyroid, hippocampus, and pineal. All of the glandular hormones dance together, interacting to guide the human body to allostasis – the best metabolic balance to survive (see ▶ Chap. 47).

5.16 Respiratory System: Lung and Sinus Illness

The oxygenation of the body is dependent on the respiratory system exchange of oxygen from the air in the atmosphere with the metabolic waste of carbon dioxide – a rhythm critical throughout life; going without for approximately 6 min or more can result in death. The health of the sinus areas as the

Table 5.4 Genomic considerations for restrictive respiratory diseases

Condition	Gene(s)	Key nutrient considerations [57]
Asthma	Alpha 1 antitrypsin [Smoking increases risk]	Vitamins C, A, D Zinc Biotin Essential fatty acids
Emphysema		
Chronic obstructive pulmonary disease (COPD)		
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator (CFTR)	Vitamins C, A, D Zinc Biotin Essential fatty acids
Lung cancer	[Smoking increases risk] ROS1 symptoms attributed to a respiratory infection	Zinc Vitamins D, A, E Essential fatty acids Immune support
Sarcoidosis	Small groups of inflammatory cells to grow in lungs	Vitamins D*, A, E Essential fatty acids (*Caution using vitamin D)
Idiopathic pulmonary fibrosis	Scarring in the lungs	Vitamins C, A, D Zinc Biotin Essential fatty acids Phospholipids
Granulomatosis with polyangiitis (GPA) ("Wegener's granulomatosis")	Chronic inflammation of lungs, kidney, and cells usually related to infection; a vasculitis; rare multisystem autoimmune disease	Vitamins C, A, D Zinc Biotin Essential fatty acids Phospholipids Immune support

first air entry point is important as hair filters in the nose protect from most particles being inhaled into the lungs. The lung has nutrient requirements of fats, oils, and proteins to maintain the structure of the lung barrier along with nutrient cofactors vitamin A, zinc, and vitamin C influencing lung metabolism. As the exchange occurs, the oxygen entering the bloodstream connects with the RBC heme to be carried and distributed to cells and tissues throughout the body. With many unique genomics that can affect the lung, knowledge of those increases the skill of the nutrition practitioner to intervene successfully for each individual (see ▶ Chap. 52) (Table 5.4).

Genotype-related risk of metabolic perturbation pathway systems and genes:

- Methylation genomics: the genomic expression related to B vitamins, phospholipids, and vitamin D. Genes: *MTHFR* 677C/1298C, *MMTR*, *MTR*, etc.
- Detoxification genomics: Glutathione-S-transferase genes (*GSTM1*, *GSTP1*, *GST*), *CYP*, and *COMT*
- Vitamin D receptor: *VDR RXR*. Vitamin D is dependent on magnesium status for its function. Vitamin D is a hormone and immune modulator in addition to the other roles in mineral metabolism and inflammation.

Because of the recognition of the unique biochemical phenotype and genotype for each individual, the current trend in medicine is toward personalized medicine [58]. Often referred to as "P4 medicine" (predictive, preventive, personalized, and participatory), the personalized paradigm for chronic disease healthcare is gaining support from practitioners of diagnostic medicine.

Biological systems are groupings of molecules, tissues, hormones, and organs that are affected by lifestyle choices and that work together to perform a common function to express as one whole human organism. Nutrients are basic co-factors for all those systems that determine their function. Common systems, such as the circulatory, respiratory, and nervous systems, need to be appreciated in the context of their interactions. The concept of systems biology focuses on interacting systems, in contrast to conventional acute-care medicine that generally considers systems as isolated entities without appreciating their interrelationships.

5.17 Potential Triggers

The five spheres of the Radial can be impacted by genetics, epigenetics, biochemical uniqueness, and microbial interactions and interplay. Imbalances can be triggered by chronic stress, toxins, pathogens, food allergens and intolerances resulting in a disruption in cells, tissues, and organ systems. These potential biological triggers are illustrated in the exter-

nal section of the Radial and can collude to harm health and fuel chronic diseases such as obesity, diabetes, cardiovascular, neurodegeneration, mental illness, autoimmune conditions, allergies, asthma, and more. Evaluating the five spheres of influence and identifying pathological insults is essential in order to reestablish systems balance, foster metabolic integrity, and promote nutritional resilience.

5.18 Stress

Chronic stress is an antecedent to health issues and is represented in the outside of the Radial. There have been many definitions of stress in the medical literature from Hans Selye's original description as "the nonspecific response of the body to any demand made upon it" to R.S. Lazarus describing stress as "a circumstance external to a person, which makes unusual or extraordinary demands on him, or threatens him in some way" [59]. The detrimental impact of chronic stress has been well documented and causes major disruptions in the neuro-endocrine-gastro-immune and musculoskeletal systems. Chronic adverse life experiences, especially psychosocial stress, have been shown to induce destructive changes to the microbiome [60].

The nutrition professional should assess the role stress plays in a patient's life by incorporating some questions in the health questionnaire that are specific to stress. This can be done with a stress rating scale where the patient scores their chronic stress level (e.g., 1 = no stress to 5 = major stress) in categories such as health, finances, relationships, and work. Referrals to clinical social workers, behavioral psychologists, integrative yoga therapists, or mind body skills groups should be made if the individual is unable to effectively manage chronic stress. In addition, some integrative nutrition professionals have advanced training in behavioral therapies and mind-body medicine and can apply those skills to a person-centered nutrition care process (see ▶ Chap. 47).

5.19 Toxins and Toxicants

It can be difficult to know when a level of a toxin will have a physiologic impact on a single person, as response to toxins is individual. Nutritional interventions have been proposed as a key prevention strategy. The impact of toxins is being identified beyond just those with work-related exposures, and evidence suggests a significant impact in seemingly everyday exposures [61]. Two primary references are the Centers for Disease Control and Prevention's (CDC) Agency for Toxic Substances and Disease Registry (ATSDR) ToxFacts sheets, which address where toxins come from and how to best test for them, and the National Health and Nutrition Examination Survey (NHANES) Fourth Report evaluates toxins assessed by NHANES from population studies, allowing the clinician to make comparisons against population values [62, 63].

Table 5.1 lists a truncated list of the ▶ Box 5.1 ATSDR 2013 Substance Priority List.

Box 5.1 The ATSDR 2013 Substance Priority List [62]

Arsenic
Testing: Urine arsenic is the most reliable test for recent exposure to arsenic (within a few days prior). Tests of hair and fingernails can measure exposure over the last 6–12 months. Most tests measure the total amount of arsenic in urine. This can sometimes be misleading because there are non-harmful forms of arsenic in fish and shellfish, which can give a high reading even if you have not been exposed to a toxic form of arsenic.

Lead
Testing: A blood test measures the amount and estimates recent exposure. Lead in blood is rapidly taken up by red blood cells and referred to as blood lead concentration (PbB) which is the most widely used and reliable biomarker for general clinical use, and reflects recent exposure, <30 days. Venous sampling of blood is preferable to finger prick sampling. Urinary lead excretion reflects, mainly, recent exposure.

Mercury
Testing: Blood or urine samples are used to test for exposure to metallic mercury and to inorganic forms of mercury. Mercury in whole blood or in hair from the scalp is measured to determine exposure to methylmercury.

Polychlorinated biphenyls (PCB)
Testing: There are more than 200 PCBs. Testing can identify if PCB levels are elevated, which would indicate past exposure to above-normal levels of PCBs but cannot determine time and length of exposure.

Benzene
Testing: Measuring benzene in blood is a common test. However, since benzene disappears rapidly from the blood, it is only useful for recent exposures. Benzene is converted to the metabolite S-phenylmercapturic acid in urine, which is a sensitive indicator of benzene exposure. Since benzene is lipophilic, it is preferentially distributed to lipid-rich tissues, so blood tests should be lipid adjusted.

Cadmium
Testing: Cadmium can be measured in blood, urine, hair, or nails. Blood shows your recent exposure to cadmium. Urine shows both recent and past exposure and can reflect the amount of cadmium in the body. However, urine test results can be impacted by kidney function.

This priority list is not a list of the most toxic substances, but rather a prioritization of substances based on a combination of their frequency, toxicity, and potential for human exposure. A biomarker of toxic exposure is a xenobiotic substance, its metabolite(s), or the product of an interaction between a xenobiotic agent.

5.20 Pathogens (See ▶ Chap. 21)

Pathogens, by definition, are a bacterium, virus, fungus, prion, or other microorganism that can cause disease. Parasites are generally larger organisms like worms, ticks, or insects that can also cause disease. The concern for parasites

is often decided based on their level of virulence. Common bacterial pathogens are *Pseudomonas*, *Shigella*, and *Salmonella*. Viral pathogens include influenza, adenovirus, rubella, and others. Examples of pathogenic fungi include *Candida*, *Aspergillus*, and *Cryptococcus*. The best-known prionic pathogen is bovine spongiform encephalopathy, also known as "mad cow disease." Pathogens can be difficult to identify and treat. In 2016, the CDC debuted the MicrobeNet Pathogen database [64], which contains information on pathogens and treatment protocols. Undernutrition puts people at a greater risk of infection and increased severity. Adequate nutritional status helps to support the negative physiologic impact of a parasite, such as increased metabolic rate, loss of appetite, immune responses, and specific nutrient requirements [65].

5.21 Food Allergies and Intolerances

There has been a notable rise in food allergies and intolerances around the globe. A food allergy is defined as an adverse health effect arising from a specific IgE immune response that occurs reproducibly on exposure to a given food. Symptoms can range from urticaria to life-threatening anaphylaxis. A food intolerance is an adverse reaction to a food or food component that lacks an identified immunologic pathophysiology. It results from the body's inability to digest, absorb, or metabolize a food or component of the food. These non-immune mediated reactions are caused by metabolic, toxicological, pharmacological, microbial, and undefined mechanisms [21] (see ► Chap. 20).

5.22 Conclusion

The Radial assimilates all the elements of a systems biology approach to healthcare (also referred to as P4 medicine) [58]. It is a paradigm-shifting model for nutrition professionals to apply in practice to engage and empower patients in self-care to achieve their highest health potential and realize their vital goals. Poor diet coupled with harmful environmental exposures and unhealthy lifestyle behaviors are causative factors driving the global burden of chronic disease.

» The truly competent physician (practitioner) is the one who sits down, senses the 'mystery' of another human being, and offers with an open hand the simple gifts of personal interest and understanding [66].

Therapeutic Relationship
This means that the doctor (or practitioner) can imagine the inner experience of the patient and practices clinically sound medicine in a way that respects that inner experience. In other words, patient-centeredness is a mindset expressed in professional behavior; and consulting skills are the translation tool between the mindset and the behavior [1].

6.1 Introduction: Solutions to Help Build Trust with Patients

While growing research is focused on how to build a therapeutic practitioner-patient relationship, the current medical paradigm has a less-than-complete understanding of how to do so [1]. Ideally, practitioners should treat each patient as a client and as such provide their clients superior customer service. Superior customer service requires individualization of patient care, which should be the focus for all practitioners. It also demands a high level of engagement with the patient, one that can lead to mutual trust. However, a high level of engagement is only possible when the practitioner is trained in the best way to interact with the patient as an individual [2, 3]. In the end, the practitioner's goal should be to foster excellent relationships with patients to deliver superior, customized personalized patient healthcare [3].

Teaching behavioral competencies, also referred to as *soft skills* (see Table 6.1 for list of soft skills), has been an important part of leadership development in the corporate world for many years [1, 2]. The development of leadership soft skills and the teaching of soft skills competencies is a missing element in healthcare training and education [1]. Providing this model of education to all types of medical practitioners would improve patient interaction, communication, and engagement while increasing effectiveness in delivering personalized patient care in a time-efficient manner [2]. Exploring the importance of understanding and using soft skills within medical practice will be our starting point. To understand soft skills, practitioners need to learn how to use multiple assessments, including those that measure personal behaviors, team behaviors, emotional intelligence, resilience, and empathy.

This chapter is intended to demonstrate useful techniques for creating stronger trust relationships with patients that will become an integral part of patient therapy. A well-prepared practitioner who understands interpersonal skills and who communicates sensitively and effectively with patients of all personality types will improve their practitioner-patient relationships. We encourage practitioners to be involved in a holistic healing process encompassing mind-body-soul to deliver personalized patient care and to encourage families to become part of the healing process. We cannot continue to confine the healing process inside of disconnected silos. Everything related to the patient healing process should be part of the same system. We need to define and improve connectivity of the totality of the health system.

Table 6.1 Description of hard skills and soft skills competencies

Hard skills	Soft skills
A degree or certificate program	Communication skill
Technology experience	Interpersonal skill
Proficiency is a foreign language	Teamwork
Machine operation knowledge	Leadership
Coding ability	Problem solving

Trust impacts us 24/7, 365 days a year. It undergirds and affects the quality of every relationship, every communication, every work project, every business venture, every effort in which we are engaged. It changes the quality of every present moment and alters the trajectory and outcome of every future moment of our lives – both personally and professionally [4].

6.2 The Need for Improved Practitioner-Patient Communication: Practitioner Know Thyself!

Educating practitioners to understand their behavior styles and to help them to improve communication skills is a missing element of healthcare education curricula [2]. When practitioners understand their preferred work behaviors, medical teams can come together and adapt their behaviors to coworkers while meeting the needs of their patients [3]. This can help teams have a more cohesive, less stressful environment while interacting with all types of patients with all types of needs. If practitioners were to be taught new interpersonal skills or soft skills for effectively communicating with patients, the practice of medicine could significantly improve. Table 6.1 lists a set of useful soft skills, compared with more commonly understood hard skills that are usually acquired through education, training, and/or life experiences. In this chapter, we focus on communication and interpersonal skills.

The most effective use of behavioral soft skills occurs when practitioners understand how to adapt their own behavioral style to meet the needs of the patient.

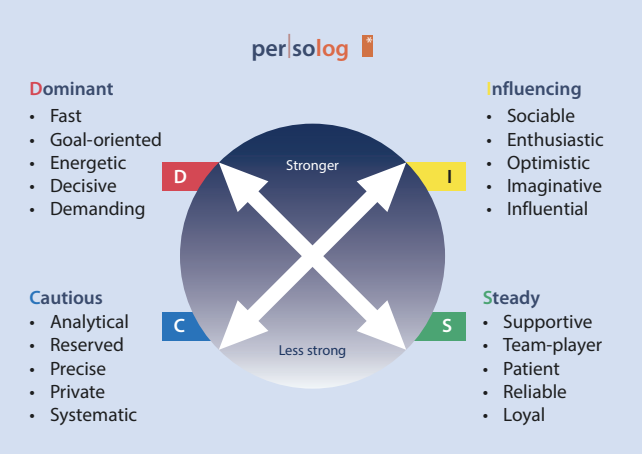

Fig. 6.1 Four behavioral styles originally described by William M. Marston in his book *Emotions of Normal People* [5] and illustrated by Persolog [6]. (Used with permission from Persolog.)

Starting in the mid-1920s, personality researchers began to develop descriptions of human personality types as they relate to personal interactions. This work was brought into focus by William M. Marston in his seminal book *The Emotions of Normal People* [5]. After being refined through further research, the description of behavioral styles has settled on terms denoted by the acronym "DISC," standing for dominant, influencing, cautious, and steady [6]. The characteristics of each behavioral style are shown in Fig. 6.1 [5, 6].

> Using skills related with human behavior in the health field is an effective way to create a stronger therapeutic relationship between practitioners and patients.

There are specific and identifiable styles of communication between practitioners and patients that can be characterized using the DISC paradigm. What follows are examples of each style of either practitioner or patient behavior. These four styles are commonly seen in healthcare settings and offer some clues toward understanding behaviors of both the patient and the practitioner:

Dominant Behavior (D) This style of patient communication is interested in receiving bottom-line information from the practitioner. These patients prefer a brief conversation and limited social interaction. They are not interested in a lot of data – just enough to hear the news and what they will have to do with the news. They may test the practitioner by asking direct questions while evaluating if the practitioner knows what they are doing. They have a need to control their environment and have a tendency to act as the authority figure. When unable to take control, they can be aggressive and demanding.

Influential Behavior (I) This type of patient seeks more communication than in the dominant type above and may want hand-holding, reassurance, and their practitioner's understanding and acceptance of their emotional state. They want to hear information in simple words and will ask a lot of questions to help them understand the diagnosis. They may want to talk at length with the practitioner and may be emotional. They don't respond well when facing a practitioner who is all business. They prefer a practitioner they consider a friend.

Steady Behavior (S) Patients with this communication style will listen and take time to digest information. They limit conversation, are cooperative, and will want to know their prognosis. Their focus when listening to the practitioner will be mainly on how their health status will impact their family. They will want to protect and remove any risk to their loved ones and want to put things in order, should their health be in danger. They do not like conflict and are congenial and thoughtful.

Conscientious Behavior (C) Patients with this style of communication focus on accuracy of the diagnosis and will review all available data shared by the practitioner. They will conduct independent research to validate the data given by the practitioner. They want the diagnostic data numbers to be very clear. If they have access to a computer during a hospitalization, they may check the information they receive from the practitioner against online sources.

For an example of two different behavioral styles and their interactions, consider a practitioner who is a dominant A-type personality, or DISC-style type D, working with a patient who has a social-interactive style type I. The practitioner will be direct and conclude the conversation in a short amount of time. The patient's expectation of how the practitioner should communicate might include asking the patient questions such as, "How are you feeling today? Have you talked to your family about your situation? Do you have any questions about what I said?" Many of these questions from the practitioner will satisfy, reduce fear, and build trust and confidence with the patient. Some practitioners naturally connect with patients. For others, informal conversation is not easy. Soft skills education will help practitioners understand numerous communication styles.

> The objective of learning to understand behavioral styles for better patient care is to increase engagement between caregivers and patients, to further build stronger relationships.

6.3 Behavioral Competency Soft Skills Improve the Practitioner-Patient Experience

Time spent in the therapeutic encounter continues to be reduced. Today, a major opportunity in healthcare presents itself through teaching behavioral competency techniques that will mitigate the patient's frustration level when the

Table 6.2 The most important behavioral competencies (soft skills)

Competencies	Some critical behaviors practitioners need to strengthen
Leadership	Remaining calm and effective in high-pressure situations Taking initiative – doing what needs to be done without being asked to do so Demonstrating high standards of ethical conduct Dealing fairly with all people Showing sensitivity and compassion for people
Teamwork	Treating coworkers with courtesy and respect Supporting decisions made by the team Putting team goals before individual goals Helping coworkers when they are having difficulty Asking coworkers about their projects and priorities
Communication	Expressing thoughts, feelings in words Explaining the reasoning behind own opinions Listening to others without interrupting Communicating in a clear, logical, and organized manner Exhibiting an open mind when hearing people's opinions
Focus on patient	Placing a high priority on improving patient service Recognizing and rewarding people who deliver excellent patient service Encouraging employees to contact and listen to patients Identifying and understanding the patient needs and service expectations Appropriately communicating with patients to keep them informed on a regular basis
Interpersonal skills	Establishing effective relationships with coworkers Showing knowledge and respect for people's responsibilities throughout the organization Establishing trust with people at all levels Taking time to establish relationships with people at all levels Demonstrating an appreciation of the value a diversity of people in the workforce

practitioner does not have enough time to listen. See Table 6.2. Using interpersonal skills adapted to human behavior is an effective way to create stronger relationships between practitioners and patients [7, 8].

Behavioral competencies are identified in terms of both hard skills and soft skills. Soft skills are frequently used in the business realm, but currently less so in medicine. Soft skills are important competencies for practitioners to have, understand, and use when caring for patients. Improving behavioral competencies (listed in Table 6.2) will improve the practitioner-patient relationship.

Using soft skills allows practitioners to consider how the patient is receiving a difficult diagnosis, for example, while simultaneously allowing the patient to understand what the medical expert is saying. If behavioral competency soft skills are not in place, the patient receiving the medical diagnosis may not be able to understand the important information the practitioner needs to deliver. Health practitioners frequently convey diagnoses to their patients using medical jargon or vocabulary that non-healthcare providers may be unfamiliar with, making it more difficult for patients to accept or process the information. If the medical practitioner does not consider how the patient is able to receive the information, then the patient can experience confusion, fear, worry, stress, and denial. The intent may be good on the part of the practitioner, but the message's impact on the patient will be ineffective.

In healthcare, practitioners would be more effective if additional educational curriculum included competencies focused on personalized patient communication.

There are definite challenges and barriers between practitioners, team members, and the patient; these challenges and barriers are, in part, communication barriers. Strengthening soft skills and enhancing communication reduces conflict and initiates cooperation and collaboration. It turns disagreement into discussion, which leads to creative solutions. Communication skills are sharpened to humanize the delivery of information to the patient and to help the patient understand the practitioner more clearly. Besides words and body language, better communication also includes allowing the patient to be heard. This reduces patient fear, resistance, and shame in the clinical setting [9–12].

The responsibility for effective communication rests with the practitioner. Focusing on meeting the needs of the patient through effective communication can help improve patient care, satisfaction, and outcomes. Enabling practitioners to learn and develop specific and critical behavioral competencies may significantly improve the level of engagement in patient interaction. In some ways, the healing process begins when patients feel they have a voice in the conversation and an audience for their story, one that listens, rather than directs, how the conversation should go.

The patient who believes their practitioner is listening to them will begin to trust and be more willing to reveal information. Information such as the possible root cause of their ailment, a trauma that could have initiated the beginning of the disease, emotional upheaval, stress they live with, fears, denial, and/or concern for their family's reaction will be shared fully. A psychologist is not necessary to uncover such background. A trained, patient-focused team can do it when it works in synergy. A term, *situational communication*, has been developed to describe this type of teamwork [12]. Please refer to the Case Study.

Case: Effective Communication to Build Strong and Trusting Patient Relationships: A Way to Personalized Patient Care

Optimal health depends on a robust practitioner–patient relationship. This relationship involves the critical need for patients and their families to have their often-unheard voices heard. Information shared in an open and safe environment contributes to the formula that will effectively change the current model of the practitioner–patient relationship. Paramount in this process is the need to examine the importance of storytelling as a means to build trust and the significance of identifying support communities when striving toward optimal health. These communities have been identified as tribes and are a rich resource and support for the patient and their families. As a new type of practitioner, it is critical to be armed with the communication resources to facilitate these trusting, healing connections.

Below is a shared story; with changes in details and variations in setting, thousands of people with similar life-altering experiences have told this type of life narrative. Important in this story is the focus on the conversation and allowing the storyteller to speak uninterrupted so as to value their experience [14, 15].

The storyteller was first exposed to a family member's serious health challenge when she was a young girl. She had a younger brother 10 years her junior who was ill from birth, and she felt compelled to help her mother care for him. He had been born with a congenital urinary disorder that was not diagnosed until he was a toddler and was eventually found to have an obstruction of the urethra, resulting in reflux with injury to the bladder and kidneys. The obstruction was surgically removed, but recurred quickly. As a result, he underwent many surgical procedures over the following years. The mother became his nurse, changing catheters, while the sister was designated as her "little helper," sterilizing the equipment and assisting in other ways. The family members were not specifically trained, but knew these interventions were necessary and critical to save the child. They did the best they could to understand the complex conversations and directions for interventions the practitioners shared, including information regarding prognosis, what treatments he required, and what to perform at home. The storyteller recalled her mother "doing everything she could possibly do to keep him alive," in addition to answering the questions about her brother's condition in a way the family could understand.

What the storyteller remembers vividly is the frustration her mother expressed in this situation, the isolation she experienced, and feelings of being incapable of providing accurate information to family and friends. She describes these feelings as "palpable." The storyteller discusses being involved throughout the remainder of her childhood until she was a young adult and no longer living at home, when she describes her support changing from direct involvement to moral support. She describes her mother providing 27 years of effective care for her brother until he died.

As the only girl in the family of four children, she had an early education in "caretaking," but believes this early education allowed her to acquire many competencies that proved to be extremely useful later in life. As the storyteller describes, "These skill sets were ingrained in me and allowed me to face one of the most challenging health crisis I never expected to deal with again. A crisis that changed my life in ways I never expected, never thought I could endure, nor survive."

By the age of 27, the storyteller was the mother of four children, all born within six years. She describes herself as a child raising children. During that time and before the development of the rubella vaccine, a rubella epidemic swept the United States. Over that short period, there were 12.5 million cases of rubella. Around 20,000 children were affected with congenital rubella syndrome (CRS), which left more than 11,000 children deaf, 3,500 blind, and 1,800 with mental retardation. There were 2,100 neonatal deaths and more than 11,000 abortions, some spontaneous because of prenatal rubella infection and others performed surgically after women were informed of the serious risks of prenatal exposure. The storyteller states 1965 as the worst year of her life and goes on to describe:

- "My one son was two years old at the time he contracted the disease (rubella). Unbeknownst to me, I was 1 ½ months pregnant. During this time, primary doctors made house calls and the doctor came to my home to treat my son. A month later, again not knowing I was pregnant, I called my doctor to inform him that I wasn't feeling good. I had a fever and felt like I was getting the flu. He suggested I take some aspirin, a warm bath, and try to get some sleep. I did exactly that, however I noticed that I had small bumps on parts of my body, so I called once again to inform him and was told that I most likely contracted rubella. After the rash had cleared, I went into the office for a blood test. It was during that visit that I found out I was pregnant. Little did I know that this event would change my life dramatically. My baby girl was born with multiple medical problems; problems that I was not aware could happen because of the rubella infection."

- "At the time of her birth, she weighed in at 3 lbs. 11 oz. and was 21 inches in length." When she reached 8 pounds, she had her first open-heart surgery at Boston Children's Hospital. At that time, neonatal care was just emerging. It was not until 1965 that the first American (neonatal) intensive care unit (NICU) was opened in New Haven, Connecticut and in 1975 the American Board of Pediatrics established sub-board certification for neonatology."

- "I had an appointment with the heart specialist to review her prognosis and prepare for her surgery. With my baby in my arms, terrified and alone, the doctor entered the room and introduced himself."

- "The doctor was all business and spoke to me in terms I didn't understand. The questions I asked were uninformed, too vague for the doctor to understand, and I was not confident enough to continue to probe. I just listened… my anxiety was at an all-time high. After about 20 minutes of listening to the doctor's information, he stood up and said his intern would be meeting with me to give me some printed information regarding my child's surgery. The surgery was scheduled for the next day. The doctor left the room, while I sat crying, holding my baby in my arms, wishing my resilient mother were with me.

- "The next person to enter the room was the intern. He introduced himself and handed me instructions and directions for the next day. I didn't hear much of what he had to say, I was still in shock at the reality of what was happening. My heart was racing, tears were flowing; I felt like a baby trying to save my child. Then, the most frightening words I ever heard came from the intern. He said, 'I'm sorry there is nothing that we can offer you to help you with your child's additional health problem.' Already confused, I said, 'What additional health problem?" He answered, 'Your child is deaf. Didn't your pediatrician inform you about this?' My reaction was filled with rage and emotion, 'You have the wrong chart. My child is NOT deaf! What kind of hospital is this? My child has a heart problem… That's all. I need to speak to the doctor!'

» "The doctor came back into the room. He tried to explain that my daughter had both health challenges, while trying to reassure me that everything would be fine. At that point, it fell on *my* deaf ears. I went into total denial. I would not accept the fact that my daughter was deaf. Even though her heart surgery was successful, I lost trust and confidence with the doctor, the hospital, and the staff. I was filled with fear for my daughter's survival. I left the hospital and drove back home in a rainstorm, with my tears flowing faster than the windshield wipers could wipe the rain away. As soon as I got home from the meeting I tried to prove to myself that my daughter was not deaf. I spent most of the rest of the day slamming cabinet doors and hitting pots together intensely watching my daughter's reaction, trying to prove that she was not deaf. I was in shock, ultimately ignorant about raising a deaf child. I had zero exposure or experience with her health challenge. The worst nightmare had just begun, and I had no way out."

The storyteller goes on to describe that 50 years later, her daughter, now a grown woman with multiple prior invasive heart procedures behind her, was facing another open-heart surgery. Due to the difficult and complex surgery she was facing, most of the extended family members were present. When the surgeon spoke to the family before entering the operating room, he was asked by the storyteller to take good care of their "little girl." She reports he replied, "I'll do my best, but this will not be easy," words not welcomed or comforting. The presurgical ritual was all too familiar for this mother as she accompanied her daughter into the OR and translated through sign language what was being communicated. Words of reassurance were signed to the daughter and received with absolute trust in her mother. Everyone in the room was supportive and kind, and the storyteller reported feeling satisfied with how events were proceeding at this point.

Although the surgery was technically a success, the storyteller reported waiting for hours not knowing if there were complications or even if her daughter had survived. Nothing from the surgeon. Finally, the family was notified that the surgery was over, led to a conference room, and anxiously waited for the surgeon to enter. When he did arrive, the storyteller reported he looked at them, did not say a word, sat down on a chair, and reviewed his paperwork. They waited until he finally said, "Oh, the surgery went well." Aside from the communication skills lacking on the part of the surgeon, the family burst into tears of relief. With each medical procedure the patient endured, she insisted the storyteller be by her side not only to interpret by signing but also to interpret the nuances of what was being communicated – or poorly communicated.

By telling her story, this storyteller was able to impart the nuanced richness of her life and life experiences and better able to project whom she is based on these experiences. If not allowed the space to tell her story, an important element of care would be lost. The practice of medicine has improved and will continue to improve, and medical practitioners are dedicated to providing best-known solutions for their patients. Patients cannot expect medical practitioners to excel in patient care when medical curriculum does not include what is currently unknown to them. Unknown curriculum subjects such as storytelling and practitioner-know-thyself training accompanied by important applicable self-assessments should be mandated in medical curriculum in order for practitioners to have the tools to be successful while providing personalized patient care.

Trust needs to be established between the medical practitioner, the patient, and the family members. Trust is inherent when communication is valued. Just as this storyteller describes, examples of poor communication can isolate patients and family members. When they are not heard, healing is not facilitated. As highlighted by this story, ineffective communication practices existed throughout the medical establishment; unfortunately, they still exist. Education to teach practitioners to hear the stories is paramount. As a new breed of practitioners, we need more focus on listening with our hearts, using better ways to acknowledge the patient's voice, and finding solutions to capture the stories, in order to realistically achieve personalized patient care.

Situational communication is a clear, concise, and focused communication strategy that maximizes the ability of a minimum amount of time to achieve successful results and effective relationships [12]. Although it may be used in personal settings, situational communication is mostly reserved for business and professional interactions, especially those that are challenging, where the points of view, interests, or preferred solutions of the communicators are different or in conflict. Leaders must be capable of planning for and executing situational communication in order to be both successful and effective. These interactions differ greatly from our mostly effortless run-of-the-mill interpersonal interactions. Situational communication represents purposeful, thoughtful engagement. In the case of situational communication, there is a planned payoff. These types of interactions are more formal, structured, and well-planned, requiring significant energy and focus [13].

In most businesses, the organization strives to help its human talent develop necessary competencies in order to be successful. In the healthcare industry, practitioners would benefit by employing the same approach. This is accomplished by adding educational curriculum that includes behavioral competencies focused on personalized patient communication with a desired effect of improved patient outcomes. Developing soft skills competencies that focus on communication skills needed by the practitioners will improve the patient's experience and make the job of the practitioner less frustrating and more rewarding.

Experts in situational communication know how to engage in robust and fruitful conversations that are tailored to the individual patient. As previously noted (Table 6.2), There are other soft skills practitioners should develop that impact the practitioner-patient relationship in addition to communication skills. All of these important skills promote a stronger trusting therapeutic relationship and improve the biological function of the human body through mind-body interactions.

Behavioral competencies should be required as part of medical curricula across all medical professions, and integrative and functional practitioners have been leading the way. When the interaction is personalized, patients can express themselves in ways that lead practitioners to understand the patient's status in a clear and concise manner. Behavioral competencies and communication skills are mandatory in any industry; however, behavioral competencies and situational communication skills will enhance the development of the therapeutic relationships that leads to successful patient outcomes.

6.4 Leading the Interdisciplinary Medical Team

There are unique competencies that all members of the medical team bring to their specific roles. One important role is leadership. Many practitioners have not been schooled in leadership competencies. However, leadership competencies are highly relevant when it comes to patient care. Members of the entire medical team (such as dieticians, physical therapists, psychologists, health coaches, pharmacists, nurses, doctors), referred to as an interdisciplinary team, need to function together in relating to a patient. The interdisciplinary team has shared leadership responsibilities, starting with understanding the principles of behavioral competency soft skills in relationship to patients.

Research states that the parts of the roles practitioners are highly competent to fill are usually roles that are personally motivating for them [13]. Excellent leaders understand that some of their roles are not self-motivating and frequently ask for feedback from the interdisciplinary team in order to gauge their own effectiveness. They seek out feedback on their leadership style. They also self-evaluate their level of effectiveness. Ineffectiveness demands leadership changes. Without the willingness to change, everything becomes static [13]. Competencies associated with corporate business are transferable throughout many industries and can be adapted to healthcare to improve patient care. Improving patient care is the ultimate outcome healthcare should strive to accomplish.

6.5 The Powerful Art of Listening: Learning to Adapt Practitioner Behaviors to Meet the Needs of the Patient

The objective of learning to understand behavioral styles is to increase engagement between caregivers and patients, ultimately building stronger relationships. Effective communication occurs when both parties have a clear understanding of their own preferred communication style. To achieve that understanding, behavioral profiling tools can help and allow the practitioner and patient to become a cohesive team. Once practitioners are trained to understand their personal behavioral style, they can quickly assess the patient's basic style, enabling both parties to better work together. Understanding the behaviors of their patients allows practitioners to change their behaviors from expecting the patient to listen and understand them, to practitioners listening and understanding the patient. More importantly, behavior assessment tools can assist interdisciplinary medical teams to understand their own preferred work behavior, so they can also learn how to adapt their behaviors to meet the needs of the patients through stronger teamwork. Utilizing assessment tools like those described below can reduce stress for the interdisciplinary team when dealing with very ill patients and challenging situations.

All of the major psychometric assessment tools in worldwide use employ the basic behaviors established by Dr. John Geier, considered the leader in human assessment science [16]. A combination of psychometric behavioral assessments (Table 6.3) can provide important data needed to properly train and prepare medical teams. Practitioners and interdisciplinary teams gain insight into their behaviors and the effect on the patient, which allows the team to be of better service. Such assessments may include emotional intelligence, DISC profile, 360-degree assessments, and performance evaluations, if appropriate. Behavioral evaluation report results are directly available to each practitioner, which opens the door for the practitioner to share results with the team to facilitate improved cohesiveness. Patients may also be assessed, and this allows the practitioner to understand his/her own behavioral style, to recognize the patient's style, and how to adapt his/her communication behavior to best address issues with the patient [18]. If medical practitioners are educated in soft skills assessments, like the ones mentioned in Table 6.2, it would enable them to recognize how individual patients choose to hear information, resulting in improved communication between the practitioner and patient. The most effective use of behavioral soft skills occurs when practitioners understand how to adapt their own behavioral style to meet the needs of the patient as discussed.

Obtaining practitioner behavioral assessments for each member of the interdisciplinary medical team enables a team-building educational process. Tools, including training modules, can teach practitioner teams how to effectively improve their communication within their medical team while understanding and respecting everyone's behavioral style. Competencies within the team are strengthened and create more concise, positive outcomes in the management of the difficult patient. In addition, for complicated patients, the combined process of tools and training is not restricted to any particular disease or diagnosis. Any medical team can benefit from data-driven assessments. These, combined with educational methodologies, should be a necessary form of education for the entire health industry.

6.6 Telling the Patient's Story

For centuries, stories have been shared through the spoken word, interpersonal conversations, diaries, and the writing of history. Storytelling has the potential to reveal emotion and psychological trauma. People remember stories. They repeat them, often linking them to their own similar experiences. No matter what the story is, if it is told, millions of people in many different languages around the world will have gone through something similar. It is that sense of connection to community that says, "I've been there; I know what that is like." Sharing stories can be an experience of enlightenment as emphasized in the Case Study.

Table 6.3 Psychometric behavioral assessments commonly used worldwide

Assessments	What the tool evaluates	Description of tools
H R Tools, Inc. ► http://HRToolsINC.com	The following tools can be located on the ► HRToolsINC.com link	See the following tools
Emotional Intelligence	Ability to characterize emotions in oneself and in others, ability to use feelings constructively and to understand and analyze emotions and solve emotional problems, ability to take responsibility for one's emotions, attaining emotional growth and maturity	The person takes the assessment and identifies what are his/her strong skills and which are the ones he/she needs to develop. Then work with a coach or participate in a training program that teaches them how to develop each skill and work on that process
DISC Profile	The DISC profile describes human behavior on the basis of four behavioral styles, dominant (D), influencing (I), steady (S), and cautious (C), and aims at a better understanding of one's own needs and those of others	There are many different programs where participants take the assessment and then work in many different training programs (also in coaching works perfectly) like teamwork, leadership, communication, interpersonal skills, and many others. The model adapts well for all these methodologies because it is based on what is my behavioral style, how I can identify other styles, and how I can adapt to them [16]
360 Assessments	This methodology consists in receiving feedback from employee's managers, peers, and direct reports. The feedback is provided by them using an online tool that ensures the confidentiality of the feedback. The questionnaire of the feedback is based on competencies and behaviors that measure those competencies or soft skills	After the 360 assessment is completed, the person receives the feedback and a consultant or coach helps him to understand it and how to work in that, as well as how to create a development plan
E4 Method	The E4 method facilitates the connection through communication and identifying teaching materials	A teaching methodology tool for practitioners to develop a standard of patient communication principles. The E4 Method was developed by Butler and Keller [17] in 1999 and is a commonly used tool

In many ways, social media holds the potential to be a healing vehicle. It provides humans an environment wherein they can tell their stories. Postings can quickly go viral; as stories are shared, experiences connect us. In this era of advanced communication technology, we have the freedom to share information and stories that instantly reach every corner of the globe.

When a patient shares their story, it helps the caregiver to understand the patient's journey and health challenges through the lens of the past and enlightens the present state of health.

As stated by Hall and colleagues, medicine is an art whose magic and creative ability have long been recognized as residing in the interpersonal aspects of patient-practitioner relationships [19]. In the healing encounter, sharing stories between practitioners and patients is one of the most important parts of the healing process. When a patient shares a story, it helps the caregiver to understand the patient's journey and health challenges through the lens of the past and enlightens the present state of health. It is critical that the practitioner understand the patient's stories so the two can build a strong connection. Much of the psychological healing process depends on this relationship. With shared experiences through storytelling, synergy and mutual trust are created. The practitioner needs to understand the patient's feelings of fear, grief, or loss, and these feelings may be mitigated if received with the type of communication the patient needs. The practitioner and patient may then connect on another level where the patient feels understood, and, in those moments of connection, the practitioner is truly serving the patient in a partnership leading to the best outcome.

To facilitate the connection through communication, teaching materials are needed. The E4 Method developed by Butler and Keller [17] is a commonly used tool for practitioners to develop a standard of patient communication principles. The E4 Method includes the following 4 Es:

- *Engagement* – skills that support development of rapport with patients
- *Empathy* – skills that help clinicians reflect concern for the patient's condition
- *Education* – skills needed for discovering and developing the patient's understanding of his/her condition
- *Enlistment* – skills that help in motivating and changing behavior

As the craft of storytelling expands, education in the field of storytelling is emerging and accessible [17]. Medical practitioners need to be educated and trained through storytelling

curriculum, which teaches understanding of the process and the uncovering of hidden meanings. Materials like the E4 Method, developed through evidence-based research, are needed to build powerful relationships and would be a beneficial addition to the medical education curriculum.

As highlighted by the E4 Method, communication between the practitioner and patient is more effective when the practitioner allows the patient to construct a timeline of their story uninterrupted. A brief conversation with the patient is often not enough and may not be satisfactory for the patient in the moment. This storytelling process has power to reveal traumas and triggers and provides a window into the current state of the patient's physical and mental health. After the patient reveals significant psychological events and stressors by sharing life's timeline, the practitioner can pinpoint important information to help in the treatment of the patient's disease. The practitioner, indicating a degree of empathy for the situation, reflects the important events back to the patient.

As a cohesive partnership develops between the practitioner and the patient, family members can be enlisted as part of the team. This will serve to educate the patient and the family about the health condition in a safe and supportive environment. Enlisting the patient and family as a team will help with motivating changes that need to be made. The team will be in sync working together toward the accomplishment of the best possible outcome. It is time for medical practitioners to reap the rewards from the soft skill of listening…listening to the stories waiting to be told, shared, understood, and accepted.

It is time for medical practitioners to reap the rewards from the soft skill of listening…listening to the stories waiting to be told, shared, understood, and accepted.

Barriers to implementing therapeutic storytelling include significant time constraints. The burden of the current healthcare paradigm with mandated abbreviated appointment times puts practitioners in a time-crunch that is not conducive to meeting the needs for personalized patient care. Practitioners expect patients to listen intently to what they have to say in this limited time, but the infrastructure of conventional care does not afford the practitioner similar time to listen to the patient. By the act of listening with intention to the patient's story and basing decisions on the shared conversation, some measure of relief of symptoms can be expected [20]. This can have the effect of reducing symptomatic complaints, shortening the length of the disease course, improving outcomes, and, in the long-term, reducing the burden of time with the patient.

Another solution to the problem of implementing and retaining the personalization in a therapeutic encounter is to depend on the contributions of the interdisciplinary healthcare team members. With common training of each team member in the art of storytelling and listening, the entire team can be called upon to effectively help when other members are unavailable. There can be building of trust, safety, and healing by wise use of team members' time.

Perceived barriers to training may also include the belief system that the practitioner is sacrificing time and energy when faced with coursework to develop communication skills. Training must emphasize the payoff of improved patient relationships, reduction in practitioner stress, improved effectiveness of time management, and healthier outcomes for patients and their caregivers. Training should be emphasized as a method to develop the skill to listen to and appreciate the patient's story which will pay dividends by providing the needed context to the patient's situation. Practitioners need to understand that this education would enable personalized patient care with effective interventions and enhancement of their skills.

We are overdue in providing the type of training necessary to change, improve, and close the gap between mediocre communication skills and high-performance communication skills. Connecting with the patient's story is critical. If practitioners are not trained in the necessary skills to connect with patients, those stories will never be heard. Training health practitioners to become proficient in storytelling and story listening is a viable potential solution to the current healthcare crisis.

6.7 Naturally Occurring Patient Tribes: The Power of Communities

Articles and methodologies are available that build on patient communities and patient support groups [21, 22]. Naturally occurring patient tribes are forming throughout the globe, and physicians, health practitioners, and health communities are not necessarily included in them. This model of patient support is becoming a powerful new way for patients to share their specific experiences and deepen their medical knowledge.

A naturally occurring tribe can be formed anywhere, anytime, and in any location. The beginning of a tribe often occurs when patients are gathered in clinical settings while waiting for treatment. In these situations, patient and caregiver tribes begin to form. What makes patient tribes different is the conversation shared between patients with shared medical challenges. Such conversations can be highly valuable for the patient and may even be more informative than a patient having a conversation with their health practitioner.

Naturally occurring patient tribes may be useful and effective for patients because individuals dealing with similar health challenges often find support in these informal connections. There may be an unspoken acceptance to engage in difficult conversations, yet facing the difficult conversation is necessary and consoling. There is a level of trust that the tribe environment creates. The trust is based on sharing information and like experiences, such as fears, doubts, and challenges with practitioners.

Patients may seek out guidance from each other, learn tips for managing their condition, and educate one another to understand the medical terminology associated with their diagnoses. People may not feel free to ask questions of their medical team, yet have no hesitancy in asking the patients or families of patients sitting nearby. There is power in this shared experience. The tribe members are on the same journey and perhaps have learned valuable things along the way. The tribe can help each other almost like a mentor helps a mentee understand specific situations and offers solutions that may be found to be extremely effective. There are many conversations about how relationships are built, how powerful they are, and how they naturally create tribes of like minds [14, 15]. This connection to the tribe is reinforced and strengthened as the relationship blossoms.

Tribes also connect and form in other ways. In today's world of technology, shared experiences go viral, and powerful connections are achieved on an unprecedented scale never before seen. Social media is an easy-to-access "share button" that connects to the world of human experiences. This global technological connectivity vehicle allows millions of people who do not know each other the ability to communicate, share stories, reveal information, and connect both intellectually and emotionally because of the thread of shared experiences.

> We want to encourage practitioners to be involved in a holistic healing process for personalized patient care and very importantly for families who should be part of the healing process.

This global phenomenon has informed many shared stories containing private information and diverse conversations in every language. This global engagement between people is powerful and has the ability to bond strangers together to become both a tribe of like minds and extended families. Evidence has emerged in recent years that reveals how powerful relationships are [21, 22]. The relationships you have and the tribe you spend time with and relate to are more powerful than even what you eat.

6.8 Conclusion

In conclusion, we cannot expect health practitioners to have skills that they have not been taught. Some health practitioners have a level of intuitive empathy and are able to fill the gap between formal education and understanding how to excel in patient communication, interaction, behavioral styles, and skills. However, all healthcare practitioners should be given the opportunity to be trained to understand the human dynamic and the diversity of each human experience. This training will be an asset to practitioners, patients, medical teams, and organizations that employ them. Communication skills are transferable and long-lasting. They may apply to other professional settings, as well as personal relationships.

When patients need information, the practitioner must give it in a clear and supportive manner. When patients need support, the practitioner must let them know they will be there for them [23]. In order to fulfill these needs and build a more effective practitioner-patient relationship, the practitioner can learn effective listening. When using effective listening, the practitioner maximizes valuable time over the long term. Effective listening allows the dialogue between practitioner and patient to be focused, informative, and positive.

In challenging settings where there may be time constraints or an undercurrent of psychological issues, the dialogue can evolve and become more productive when the practitioner attempts to understand the needs of the patient and puts the patient first. By being sensitive about word choice learned through training sessions, practitioners can make headway toward fruitful communication and let the patient know they understand where the patient is in the moment. It is important for many patients to hear and understand this. In addition, practitioners would do well to communicate with patients' families. Family members often deal with the shock of the illness of their family member and may put their feelings aside in order to cope and manage the medical situation. This situation can be acknowledged and validated. The practitioner needs to realize the family members have their own stories and can offer important insight into the history and status of the patient. Stories reveal important information indicative of their culture, family medical history, and genetic information. Families share stories. Stories have power.

The tendency to organically form support groups or tribes in medical office waiting rooms, social media, or other social venues is an important part of patient healing that healthcare teams could tap. If practitioners can develop ways to understand their patients' tribes and reinforce information shared, positive clinical outcomes will be fostered and enhance the practitioner's effectiveness and efficiency.

The time is overdue to identify and adjust the human factors that create barriers to build strong relationships. The differences in human behaviors are vast, unique, diverse, and can be complicated. However, as human beings we strive to be understood, respected, and included. It will take a concentrated effort to work to eliminate the barriers that separate us. The solution is to first understand our own behaviors and behavioral limitations, and work to improve them. "Knowing thyself" can be daunting and frightening. It will however be enlightening.

As practitioners, taking accountability for how we behave when we communicate to patients puts the onus of responsibility where it should be – on ourselves! Honing communication skills is worth the effort. These skills will improve our own lives, as well as the lives of others. When in the driver's seat, we hold the power to make or break relationships. The reward for taking responsibility and accountability for the effective way we communicate, listen, and respond to each other is a powerful reward for all of us humans. It will unite us in our effort to change and build a powerful and healing tribe of like minds.

7.1 Introducing Metabolic Correction

Metabolic correction (MC) is the utilization of a synergistic combination of micronutrients and cofactors in their active forms and proper doses to maximize the function of metabolic enzymes [1–3]. MC helps improve or rectify biochemical disturbances that disrupt normal physiological processes and may originate degenerative diseases. MC is the fine-tuning of the cellular biochemistry by means of specific, targeted nutritional supplementation with the goal of improving cellular, tissue, organ, system, and organism function [1–3]. Impaired or incomplete cellular biochemical reactions are amended with MC.

MC is a functional biochemical/physiological concept that explains how improvements in cellular biochemistry help the body achieve metabolic or physiologic optimization [1–3]. The MC concept provides the biochemical elucidation of the utilization of nutrients for preventive and therapeutic purposes against disease. The MC concept becomes important since our food is decreasing in nutritional value [4]; diseases increase the demand for nutrients, and medications can deplete nutrients [1]. These nutrient insufficiencies are causing enormous costs due to increased morbidity and mortality. In summary, MC increases enzymatic function that enhances biological functions contributing to better health and well-being.

7.2 Implications of Subclinical Nutrient Deficiencies (Nutritional Insufficiencies)

A nutritional deficiency is defined as an inadequate supply of essential nutrients (vitamins and minerals) in the diet, resulting in malnutrition or disease. Tissue levels are low enough in one or more nutrients that pathology results primarily from the nutritional deficiency and from secondary complications. Nutrient deficiency is described in medical pathology textbooks; unfortunately, this is the start and end to nutritional education for most physicians. A *nutritional insufficiency* is a subtle deficiency of a nutrient sufficient to affect health but not severe enough to cause classic index deficiency symptoms. Problems here are more of a functional/biochemical nature rather than pathologic, but they may lead to the disease state. A *nutrient dependency* refers to a unique genetic or acquired dependency on supra-dietary levels of one or more nutrients [1].

Clinical assessment of nutritional status has long been exclusively focused on detection of absolute nutrient deficiencies by relying on clinical evidence of signs and symptoms of classic nutritional deficiency states (e.g., bleeding gums with vitamin C deficiency or mouth redness and sores with b-vitamin deficiencies). Yet, relative nutrient deficiencies or insufficiencies due to disease are equally important, as is the detection of nutrient imbalances before clinical evidence of deficiency is present. At the point where altered cellular function has evolved into clinical manifestations of nutrient deficiency, cellular activity will have been compromised for some time, and the compensatory responses that might have allowed a temporary adjustment to the deficiency would no longer be effective. Detection of subclinical changes in cell processes early in the course of a nutrient deficiency, when cell damage is minor and more reversible, can have a considerable impact on the prevention and treatment of disease. If subclinical deficiency is not corrected by providing the lacking nutrient, then prolonged marginalization of cellular activity may not only increase vulnerability to disease, but it may also exacerbate progression of existing disease and interfere with effectiveness of treatment, since all drugs require some level of metabolic support to achieve their desired therapeutic effects.

7.3 Nutrient Requirements of Disease States

Diet and nutrition are important factors in the promotion and maintenance of good health throughout the entire life course. A change in metabolism occurs following injury, stress, or infection, characterized by the need for increased macronutrients and enzymatic cofactors (micronutrients). The involvement of nutrients in cellular defense and repair systems suggests that nutrient requirements are modified by pathology. In disease, nutrient-dependent activities are expanded to include effects that enhance cellular responsiveness to treatment and accommodate accelerated rates of metabolic activity. Although specific nutrient requirements for different diseases have not been established, they may be

imputed from current knowledge of the chemical, physical, and biological properties of each nutrient, the nature of the disease, the physiology of tissues involved, the type of treatment indicated, and the cellular activities targeted by the treatment.

7.4 Vitamins and Minerals and Hidden Hunger

Vitamins fall into two general categories: water-soluble and fat-soluble. Water-soluble vitamins are found mainly in watery or starchy foods such as grains, fruits, and vegetables, while fat-soluble vitamins are found mainly in fatty foods such as butter, nuts, olives, seafood, and organ meats. Only water-soluble vitamins function as coenzymes, while cofactors can also be minerals and other micronutrients (Fig. 7.1).

Vitamins, minerals, and other micronutrients play critical roles in a wide variety of highly complex and integrated cellular processes in human biochemistry. The rate and extent of the enzymatic activity that determines these processes depend on the bioavailability of these micronutrients. The healthy state where optimal (maximum) functioning, health, and well-being are achieved may be attained by *metabolic optimization therapy*. Metabolic optimization is achieved when we provide the metabolism the necessary components (form and dose) to reach full velocity and completion of biochemical reactions to attain an optimal metabolic equilibrium. Thus, metabolic optimization therapy uses a combination of genetic makeup, diet, trauma, diseases, infections, toxins, and environmental stressors, among others, which will often elevate the demand of nutrients in order to achieve this optimal metabolic equilibrium. It can be argued that the true importance of vitamins in human biochemistry is far from fully elucidated, simply because of the high complexity of cellular processes. What is commonly ignored and not fully appreciated is the essential role that various vitamins and minerals play in functional human biochemistry. Critical enzymes require vitamins and minerals as an integral part of their molecular structure and/or functional mechanism of action. Enzymes play a critical role in regulating and orchestrating the rates of the multitude of biochemical reactions that take place in living organisms.

Vitamin deficiencies or coenzyme deficiency can lead to serious health disorders because important biological processes break down when a lack of coenzymes prevents enzymes from catalyzing essential chemical reactions [5]. Two well-known coenzyme vitamins are thiamin and niacin. Thiamin compounds serve as coenzymes for a variety of reactions involving cellular energy production, protein synthesis, and brain function. Thiamin deficiency causes a disorder known as beriberi, with symptoms such as irritability, weakness, and even heart failure. Niacin is needed for numerous reactions related to energy production and fatty-acid synthesis. Deficiency causes pellagra, which leads to dementia, skin problems, weight loss, and eventually death.

Inadequate or insufficient dietary intakes of vitamins and minerals are widespread [4], most likely due to excessive consumption of calorie-rich, nutrient-poor, refined food. Suboptimal intake of micronutrients often accompanies caloric excess (hidden hunger). *Hidden hunger* (or occult hunger) is a form of undernutrition in which a chronic lack of vitamins and minerals has no visible warning signs. Hidden hunger refers to subclinical deficiencies or nutrient insufficiencies from which our population suffers because of our excessive consumption of calorie-rich, nutrient-poor, refined food. This may be the basis of metabolic disruptions that underlie many pathological/disease states. Since we are not eating enough of the proper nutrient-dense foods, what we end up eating contains insufficient vital nutrients and excessive calories. The Standard American Diet lacks essential nutrients. This state of nutritional insufficiency is a possible reason why millions walk around with headaches, body aches, digestive upset, skin problems, sinus problems, frequent colds, and other signs and symptoms that may quickly disappear when you start taking necessary vitamins and minerals. Nutrition is enhanced through supplementation.

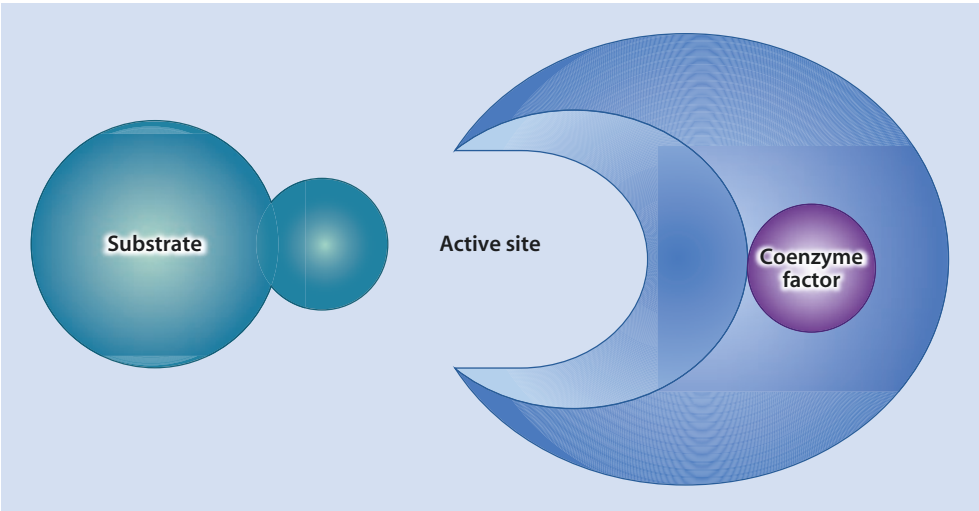

Fig. 7.1 Water-soluble vitamins function as coenzymes

Hidden hunger can lead to mental impairment, poor health and productivity, or even death.

These inadequate intakes may result in metabolic disruptions [6]. Episodic shortages of micronutrients were common during evolution. Natural selection favors short-term survival at the expense of long-term health [6]. Short-term survival was achieved by allocating scarce micronutrients by nutritional *triage* [6]. As micronutrients become scarce, a triage mechanism for allocating scarce micronutrients is activated. This triage (mechanism) means prioritization of relatively scarce nutrients to the most fundamental life-preserving functions. In metabolic reactions, enzymes involved in adenosine triphosphate (ATP) synthesis would be favored over deoxyribonucleic acid (DNA) repair enzymes, as well as over the production of immune system components and neurological chemicals [5]. When there is a lack of synergistic components of the metabolic network, an array of negative metabolic repercussions arise, eventually leading to loss of healthy physiological equilibrium and the development and progression of degenerative diseases.

» This triage (mechanism) means prioritization of relatively scarce nutrients to the most fundamental life-preserving functions.

Michael J Gonzalez, DSc, NMD, PhD, FACN
University of Puerto Rico Medical Sciences Campus, Schools of Public Health[1], Department of Human Development, Nutrition program
San Juan PR

The triage theory of optimal nutrition states that the human body prioritizes the use of vitamins and minerals when it is getting an insufficient amount of them to be able to keep functioning [6]. Triage means deciding which patient to treat when faced with limited resources. When nutritional resources are limited, physiology (biological intelligence) must decide which biological functions to prioritize to give the total organism and the species the best chance to survive and reproduce. While short-term deficiencies or insufficiencies are common, they are often not taken seriously by mainstream medicine. Under such a limited scenario, the body will always direct nutrients toward short-term health and survival capability and away from regulation and repair of cellular DNA and proteins, which ultimately optimize health and increase longevity. Dr. Ames's research shows how bodily insults accumulate over time as a result of vitamin and mineral insufficiencies and can lead directly to age-related diseases. The Triage hypothesis states that the risk of degenerative diseases (those associated with aging, including cancer, cognitive decline, and immune dysfunction) can be decreased by ensuring adequate intake of micronutrients [5–9].

7.5 Why Metabolic Correction?

Metabolic correction therapy is indispensable because of these specific issues:

7.5.1 Inferior Nutritional Value of Food and Low Availability of Nutrient-Dense Foods

We need to eat a wide variety of food to obtain the nutrients we need. A big problem we face is that the nutritional values of foods that people eat may be inferior to the listed values given in food tables. Foods today have less nutrient content than foods 50 years ago. A study that assessed this issue showed declines in protein (−6%), calcium (−16%), phosphorus (−9%), iron (−15%), riboflavin (−38%), and vitamin C (−20%) [4]. There is a dilution effect, in which yield-enhancing methods such as fertilization and irrigation may decrease nutrient concentrations. Recent evidence suggests that genetically based yield increases may have the same result, a genetic dilution effect. Modern crops that grow larger and faster are not necessarily able to acquire all the necessary nutrients, whether by synthesis or from the water and soil. Today's foods are not as nutritious as those eaten in the past. A report from the US and UK Government statistics shows a decline in trace minerals of up to 76% in fruit and vegetables over the period from 1940 to 1991 [10, 11]. The nutritional decline findings alone give reason to eat organic fruits and vegetables. In fact, for nearly all nutrients, organic fruits and vegetables remain the most nutrient-dense foods [12]. This information makes the updated nutritional recommendations not so much current as reflective of the need for an increase in fruits and vegetables in order to get the same nutritional benefits as in the past. It is likely that Americans do not come close to the recommendations to limit added sugars, refined carbohydrates, and added fats and oils.

7.5.2 Medication-Induced Nutrient Depletion, Adverse Side Effects of Medication, and Iatrogenic Deaths

There are more than 100,000 deaths annually due to medication properly prescribed and taken as directed by the health provider [13], resulting in extremely high incidence of serious and fatal adverse side effects in US hospitals – more frequently than is generally recognized. Fatal adverse side effects appear to be the fourth leading cause of death in the USA [13]. If medication is necessary, providing metabolic correction principles may reduce medication requirements, reduce adverse side effects, and improve treatment outcomes [14].

7.5.3 To Compensate for the Increased Demand of Nutrients due to the Disease State

The body's nutritional demands increase in acute and chronic illness [15]. These imbalances are mainly caused by either deficiencies or insufficiencies of one or more nutrients. Nutrients function in disease by mechanisms that differ substantially from those of pharmacologic agents. Nutrients will modify nutrient fluxes and metabolic activities that are part of cellular processes needed for physiological repair, correction, and/or balance, whereas drugs will bind to membrane receptors and modify their activity to alter cell responsiveness. Nutrient requirements in the presence of disease are considerably higher than those that have been established to prevent the symptoms of the classic deficiency diseases. These requirements can increase incrementally by as much as 10 to more than 100 times the usual amounts (orthomolecular medicine) [16]. At these levels of intake (some at pharmacological doses), the roles for most nutrients are expanded to include functions that are not typically observed at normal intakes. The higher requirements for nutrients in disease are needed to support the accelerated rate of metabolic activity that cellular systems demand in order to reduce the potential for permanent damage from the pathophysiological processes associated with the disease.

Nutrient imbalances impose a metabolic burden on all organ systems, with the greatest burden on those systems responsible for achieving and maintaining metabolic equilibrium. Long-term disruption of metabolic equilibrium will most often adversely impact the cardiovascular, pulmonary, renal, gastrointestinal, neurological, and/or musculoskeletal systems. In the absence of an adequate supply of nutrients to satisfy normal physiological requirements or adjust to increased metabolic demand, compensatory mechanisms involving one or more of these systems must be initiated to re-establish homeostasis. As with metabolic adjustments to address short-term nutrient deficiencies, these compensatory responses are important for correction of temporary imbalances, but if sustained over the long term, they may become maladaptive and contribute to the degenerative changes responsible for development or worsening of chronic diseases. For example, burns lead to loss of protein and essential nutrients [17]. Surgery increases the need for zinc, vitamin C, and other nutrients involved in cellular tissue repair [18]. Broken bones need calcium, magnesium, and vitamin C for healing [19]. Infections challenge the immune system and place high demands on nutritional resources such as zinc, B-complex vitamins, and vitamin C [20]. The same nutritional demand is present when exposed to chemical, physical, and emotional stress.

People taking medications for chronic diseases are at higher risk of interactions between these drugs and nutrients. There are thousands of conceivable genetic defects (inborn or acquired), so it is likely that many people have higher genetic requirements for many micronutrients. This discussion seeks to provide a needed better understanding of the interrelationship between nutritional biochemistry and the disease-pathological state.

7.5.4 Biochemical Mechanism of Metabolic Correction: Molecular Concentrations and Rate of Reactions

The majority of the chemical reactions in living organisms are catalyzed by enzymes. The mechanisms of enzyme-catalyzed reactions involve [1] the formation of a complex between the enzyme and a substrate and [2] the breakdown of this complex to form the products of the reaction. The rate-determining step is usually the breakdown of the complex to form the products. Under conditions such that the concentration of the complex corresponds to equilibrium with the enzyme and the substrate, the rate of the reaction is given by the Michaelis–Menten equation [21].

A certain amount of energy, known as activation energy, is needed to initiate any chemical reaction. The fundamental purpose of enzymes is to facilitate reactions by lowering the activation energy. Enzymes accomplish this by binding to reactant molecules and allowing them to interact in a more energy-efficient manner. Reactant molecules bind to enzymes at an intricately structured location known as an active site, and the molecule involved in this binding process is called the substrate. Coenzymes, some of which are vitamins and some of which are synthesized directly from vitamins, activate enzymes by helping the enzyme to bind to its substrate.

Cofactors (vitamins, minerals, and other compounds) work as enzyme assistants. Coenzymes activate enzymes primarily by assisting the transfer of specific particles or compounds involved in the chemical reaction. For example, some coenzymes facilitate enzymatic reactions by carrying electrons and hydrogen ions from one atom to another, while others are involved in transporting the entire atoms or larger molecules. Explained another way, an enzyme might not be a perfect fit for the intended substrate unless the active site is modified by the addition of a coenzyme (Fig. 7.2).

The rate of an enzyme-catalyzed reaction is approximately proportional to the concentration of the reactant, until concentrations that largely saturate the enzyme are reached. The saturating concentration is larger for a defective enzyme with decreased combining power for the substrate than for the normal enzyme. For such a defective enzyme, the catalyzed reaction could be made to take place at or near its normal rate by an increase in the substrate concentration. This mechanism of action of gene mutation is only one of several that lead to disadvantageous manifestations that could be overcome by an increase in the concentration of enzymatic cofactors. These binding problems may result in metabolic inefficiency with the accumulation of metabolic

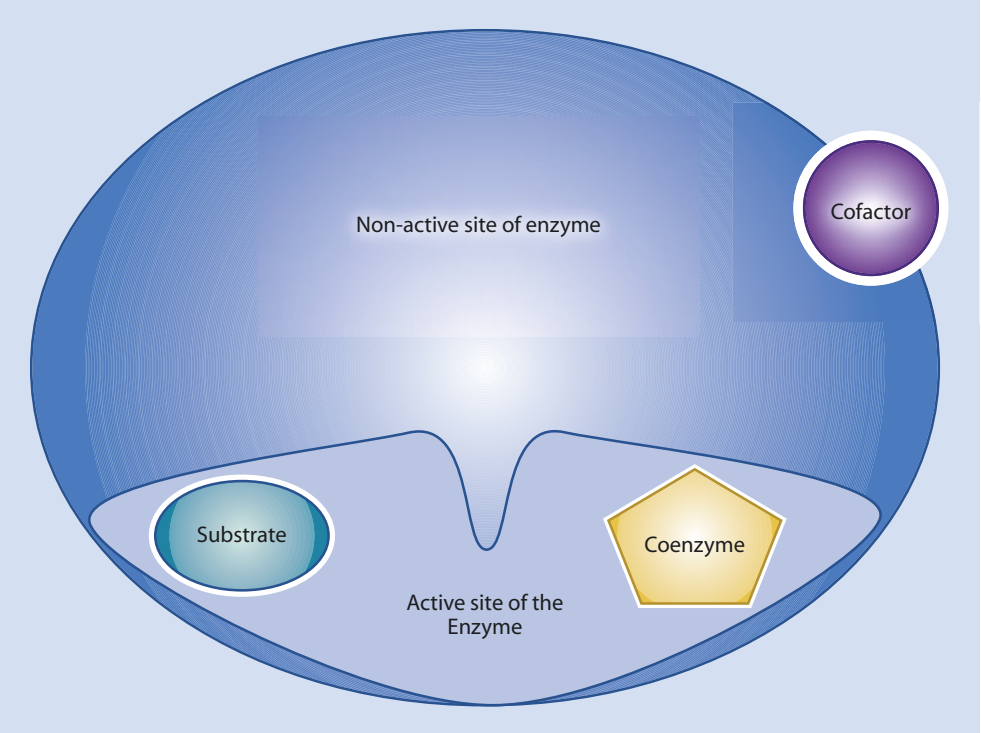

Fig. 7.2 Coenzymes bind to the reactant active site substrate of the enzyme, with cofactors as "helper molecules" that assist in biochemical transformations

byproducts. In general, this is the *Law of Mass Action*: As the vitamin and mineral concentration increases, enzyme efficiency increases. These considerations suggest a rationale for metabolic correction to provide the needed cofactors in the amount needed to improve function. This increased enzyme efficiency may allow a genetic defect to be overcome. This biochemical activity follows the chemical *Principle of Le Chatelier*, which states that when stress is applied in an equilibrium situation, it will move to the direction to minimize stress. In this case, there is an unfavorable equilibrium of active enzyme that, with the addition of the necessary nutrients, will be moved toward a more physiologically favorable metabolic state [22].

Many human genetic diseases due to defective enzymes can be remedied or ameliorated by the administration of high doses of the vitamin component of the corresponding coenzyme (metabolic correction), which can partially restore the enzymatic activity [5]. For several single-nucleotide polymorphisms in which the variant amino acid reduces coenzyme binding, enzymatic activity can be remedied by raising cellular concentrations of the cofactor through high-dose nutrient therapy (orthomolecular therapy).

Inadequate intakes of vitamins and minerals from food can lead to DNA damage, mitochondrial decay, and other pathologies [3]. Ames suggests that evolutionary allocation of scarce micronutrients by enzyme triage is an explanation of why DNA damage is commonly found along with micronutrient deficiency [3]. This particular situation favors the development and progression of diseases. Moreover, Motulsky has argued that many of the common degenerative diseases are the result of the imbalance of nutritional intake and genetically determined needs [23, 24].

Chromosome breaks lead to mutations that precede tissue damage and disease. Many types of physiological impairments due to inadequacy of vitamins and minerals can lead to suboptimal organ system function, including poor drug metabolism, insufficient neurotransmitter production, and impaired immune defenses. Chronic vitamin–mineral undernutrition reduces immune competency and central nervous system efficiency; it may increase morbidity, which may lead to degenerative diseases. This approach to optimize health by improving enzyme efficiency, and thereby metabolism and physiology, is the basis of metabolic correction as a therapeutic approach.

7.6 B-Complex and Metabolism Briefing

The basic B-complex consists of a group of eight water-soluble compounds: thiamin (vitamin B1), riboflavin (vitamin B2), niacin (vitamin B3), pantothenic acid (vitamin B5), pyridoxine (vitamin B6), cobalamin (vitamin B12), folate (vitamin B9), and biotin (vitamin B7). Although each B vitamin is chemically distinct, they often work together in various biochemical functions throughout the body, from cellular energy production to healthy red blood cell formation to

healthy neurological function. Most B vitamins, with the exception of vitamin B12, are not stored in the body. They must be acquired daily from the diet in order to maintain optimal health.

Supplementing with bioactive B vitamins (e.g., methyl folate) is important to everyone, especially individuals who may not be able to convert inactive or synthetic vitamins to their active forms in the liver because of compromised liver function, poorly functioning enzymes, digestive disturbances, genetics, or age. Dietary supplements containing these active cofactors have enhanced bioavailability, ensuring the body gets the nutrients it needs.

Every process that goes on inside our bodies requires energy, specifically metabolic energy. When the body does not have enough energy to function properly, different components of the body may malfunction in their own ways. For example, if the brain does not have enough energy, cognitive processes, such as memory and focus, may become impaired. The body converts fats, sugars, and proteins into ATP that is then used for energy. However, there are other factors involved that can affect how well our body can make this conversion into the ATP molecules. The thyroid hormones are essential in maintaining and regulating the body's metabolism. The thyroid gland makes the hormone T4 (thyroxine). T4 converts to T3 (triiodothyronine) and RT3 (reverse T3, rT3). T3 turns on the ATP (energy), while RT3 is a way to get rid of any unneeded T4, thus reducing energy output. This happens because the adrenal glands are too weak to handle the stress of the body's normal metabolic energy and force a downregulation of energy production.

Triiodothyronine (T3) is the most active thyroid hormone. Approximately 85% of circulating T3 is produced by mono-deiodination of thyroxine (T4) in tissues such as the liver, muscle, and kidney. Production of these thyroid hormones is controlled by TSH (thyroid-stimulating hormone), which is released by the pituitary gland in the brain. The pituitary takes its orders from the hypothalamus. The adrenal glands, located on top of each kidney, help the body deal with stress. If the metabolic activity is excessive, the adrenals perceive this as a stress. In response to this stress, the hypothalamus will signal the pituitary to produce less TSH, thus producing decreased T4 and thyroid activity. This metabolic control activity utilizes various enzymes whose main cofactors are B-complex vitamins.

Lack of B vitamins may lead to hypothyroidism because the thyroid gland cannot make enough T4 [25]. Hypothyroidism is a condition in which an underactive thyroid gland produces less than optimal amounts of thyroid hormone. A lack of the thyroid hormones can lead to fatigue, constipation, hoarse voice, puffy face, unexplained weight gain, pain and stiffness in the joints, muscle weakness, sensitivity to cold, elevated cholesterol levels, brittle nails, and depression. Hypothyroidism has also been linked to other health issues, such as heart disease, infertility, autoimmunity, and obesity.

7.7 B-Complex and Metabolic Correction

B-complex vitamins are essential for optimum metabolism. Michaelis developed a set of mathematical expressions to calculate enzyme activity in terms of reaction speed. The Michaelis constant Km is defined as the substrate concentration at half the maximum velocity. For practical purposes, Km is the concentration of substrate that permits the enzyme to achieve half of its maximum activity.

An example of metabolic correction is that high-dose B vitamins can counteract a poor Km. As many as one-third of mutations in a gene result in the corresponding enzyme having an increased Km (decreased binding affinity) for a coenzyme, causing a lower rate of reaction [5, 7]. About 50 different human genetic diseases are due to a poorer-binding affinity of the mutant enzyme for its coenzyme. This can be corrected by feeding high-dose B vitamins, which raise levels of the corresponding coenzyme; many polymorphisms also result in a lowered affinity of enzyme for coenzyme [5, 7] and thus may be, in part, remediable.

To summarize, metabolic correction has three important biological actions:

1. Optimizes cellular function by improving enzymatic efficiency
2. Produces a pharmacological effect to correct abnormal cell function due to biochemical disarray occasioned by the disease process
3. Provides a compensatory response to nutrient imbalances in order to re-establish physiological homeostasis

An optimum intake of micronutrients and metabolites – which varies with age, environmental factors, and genetics – should tune up metabolism and markedly increase health at a modest cost, particularly for the poor, obese, and elderly [7].

7.8 Ten Principles of the Concept of Metabolic Correction in Disease Therapy

1. *Metabolic correctors*, along with proper nutrition, should come first in medical treatment. Knowledge of the safe and effective use of nutrient combination, enzymes, hormones, and other naturally occurring molecules in their bioactive forms is essential to ensure an effective outcome. However, some patients may need more acute treatment for their particular condition, for which pharmacological therapy is recommended.
2. *Metabolic correctors have a low risk of toxicity.* Pharmacological drugs often carry a risk of negative side effects and, in a chronic condition, should be the second choice if there is a metabolic correction alternative available.

3. *Detect nutrient deficiencies*: Some laboratory tests might be useful in identifying the nutritional needs of some patients. These tests could be of special importance to patients who present genetotrophic diseases or genetic polymorphism associated with specific conditions. However, some laboratory tests do not necessarily reflect nutrient and enzyme levels within specific organs or tissues, particularly in the nervous system. The need for laboratory testing for nutrients varies among individuals. For many patients, therapeutic trial and dose titration is often the most practical therapy approach, especially when utilizing synergistic metabolic correction formulations.
4. *Biochemical individuality* is a central precept of metabolic correction. Hence, the search for optimal nutrient combination doses is a practical issue. Doses of nutrients and their combinations above the recommended daily allowances are often effective. Many patients tolerate optimal doses and respond well; however, dose titration is indicated in otherwise unresponsive cases.
5. *Recommended daily allowances (RDA) for diseased individuals*. RDAs for nutrients are intended for normal, healthy people. By definition, diseased patients are not normal or healthy and not likely to be adequately served by obtaining just the recommended daily allowances. Practically every person is deficient or insufficient in a nutrient at some level due to an insufficient diet among other limiting factors (genetics, medication, toxins, etc.).
6. *Environmental pollution* of air, water, and food is an increasing problem and more common than is generally recognized, posing a very important risk factor for mitochondrial damage and related diseases such as cancer and neurometabolic disorders [26, 27]. Diagnostic search for toxic pollutants and treatment is necessary to identify these factors and design a proper treatment approach.
7. *Monitor and update metabolic correction over time*. Optimal health is a lifetime challenge. Biochemical needs change, and our metabolic correction prescriptions need to change based upon follow-up, repeated testing, and therapeutic trials to permit fine-tuning of each prescription and to provide the best possible health outcome.
8. *Nutrient-related disorders are always treatable*, and deficiencies and insufficiencies are curable. Most diseases encounter some nutrient-related disruption. To ignore their existence is malpractice.
9. *Nutrigenomics and pharmacogenomics*. Genetic and hereditary disorders are often responsive to metabolic correction because it takes advantage of nutrigenomics and pharmacogenomics [28].
10. *Inspire active role-taking responsibility for your health*. Inspire patients to understand that health is not merely the absence of disease, but the positive attainment of optimal function and well-being. This requires an individual to take an active role in necessary lifestyle changes, and it requires a commitment to continuous education along with a responsible attitude about health.

7.9 Beyond Metabolic Correction: Improving the Healthcare Management Model

Metabolic correction should be a fundamental consideration of a complete healthcare plan, and the fundamental root causes of the prevalent conditions must be identified and addressed to achieve optimal therapeutic results. Unfortunately, medical guidelines often do not assess these root causes of disease in each individual case. Therefore, comprehensive laboratory testing is mandatory to identify etiological factors and monitor progress toward the desired outcomes. This approach allows for correlating objective laboratory tests with functional evaluations and patient signs and symptoms. We know that a certain combination of nutrients can improve physiological function. However, giving the necessary nutrients will have limited results if environmental contaminants such as pesticides, heavy metals, medications, or an undetected chronic infection are affecting the patient. Therefore, to achieve metabolic correction and the best physiological function possible, it is necessary to correct the underlying cause of the problem. This involves providing the necessary nutrients for repair, correction, and improved enzymatic activity, which must include removing the contaminants present [29].

» Metabolic correction should be a fundamental consideration of a complete healthcare plan, and the fundamental root causes of the prevalent conditions must be identified and addressed in order to achieve optimal therapeutic results.

Michael J. Gonzalez, DSc, NMD, PhD, FACN

San Juan PR

To improve outcomes beyond current standards, it is necessary to improve our health models to include detection of all significant underlying causes of disease. In addition to a comprehensive medical history and a complete physical examination, there should be comprehensive laboratory testing that includes whole-genome sequencing, inflammation, immune testing, heavy metals, xenobiotics, nutrient, food intolerance/sensitivities, and metabolic panels for a complete patient assessment.

7.10 Conclusion

To encourage the most efficient metabolism, we need basic macronutrients required for fuel: fat, protein, and carbohydrate. But we also need about 15 vitamins that are coenzymes and about 15 minerals that are required for enzyme function.

We also need two essential fatty acids (omega-3 and omega-6) and seven or eight essential amino acids. In addition, other important nutrients – such as coenzyme Q10, acetyl-L-carnitine, and lipoic acid – must also be considered in our quest for physiological optimization. Virtually every metabolic pathway requires micronutrients.

What determines the optimal concentration of a nutrient is its physiological functionality. While most people function below 100% efficiency, they nevertheless do not present any detectable disease or significant symptoms. Yet, we can improve their functionality if we supply them with the needed micronutrient substances in optimum concentrations. Certain individuals have a greater need than that supplied by the diet (even if a good dietary regime is followed). This could be caused by an array of variables (digestive problems, malabsorption, food sensitivities, metabolic dysfunction, low levels of neurotransmitter precursors, etc.). This lack of needed micronutrient cofactors manifests insidiously and is difficult to identify. Some vague symptoms may be present, such as lethargy, irritability, insomnia, and difficulty in concentrating. This also affects the body's ability to resist disease and infection, its ability to recover from exercise, surgery, or disease, and the ability of the brain to function at an optimal level. Detecting and treating disease at its earliest stages of cellular biochemical abnormality, rather than waiting for clear clinical symptoms, is cost-effective and of benefit to the patient.

Nutrient deficiency diseases are the end product of a long and complex series of nutrient depletion reactions. We need to abandon outdated paradigms framing nutrient intake as needed merely to prevent deficiencies and expand them to include preventing chronic degenerative diseases and achieving optimal health. Metabolic correction provides the biochemical–physiological explanation of how to achieve this state of metabolic harmony and health. Metabolic correction therapy used as a comprehensive model can provide a systematic, rational, evidence-based, proactive, individualized, and integrated decision-making process. That process should be evaluated by a trained health professional understanding metabolic correction for its potential to elevate our standards for cost-effectiveness and outcome improvement.

8.1 Introduction

The field of integrative and functional nutrition is expected, by its very nature, to be progressive and on the cutting edge of new concepts in nutrition. Patients in desperate need of healing seek out reliable, valid, and progressive solutions from their nutritionist. The constant barrage of changing nutritional recommendations should teach integrative and functional nutrition practitioners to hold the principle of nutritional balance at the core while new findings continue to come forth.

Fad diets and supplements will come and go through the decades, and it is important to always question the long-term consequences of every proposed new nutritional concept. Concurrently, nutritionists must keep an open mind for something that may help a patient with a puzzling condition. What may seem extreme and/or inappropriate for one person may be lifesaving for another. Many human genetic diseases, due to defective enzymes, may be ameliorated by high doses of specific nutrients required as cofactors for the enzyme to partially restore activity of that enzyme [1]. Over the lifespan, metabolic and biochemical needs change and nutritional balance should be periodically reassessed and rebalanced [1]. Furthermore, detecting and addressing disease at its earliest stage of biochemical imbalance, rather than waiting for the condition to progress to a diagnosed disease, is a cost effective and physiologically beneficial approach for the patient.

"Biochemical individuality," first proposed by Roger J. Williams in 1947, refers to differing metabolic needs for optimal physiological function and infers that nutritional balance for one person may require different amounts of nutrients than for another person [1]. One of the foundational principles of integrative and functional nutrition is to recognize each person's unique nutritional needs. If practitioners rely on nutritional studies as a guide to establishing optimal nutrient intake for individuals, as opposed to using individualized nutrient assessment, this may pose challenges. For instance, many nutrition studies fail to show a benefit of supplementation due to flawed study design, as investigators often fail to establish baseline nutrient status of study participants to accurately measure outcomes [2]. Testing and retesting may be one of the most helpful tools to keep clients' nutritional status in balance and provide metabolic correction. Integrative and functional nutritionists have a vast array of tools to choose from in this regard.

To assess nutritional imbalance, a clinician can use a nutritional physical exam, conventional and integrative laboratory testing, as well as signs and symptoms. When imbalance is found, such as a zinc deficiency, calling for diet change and supplement intervention, one must then pay attention to the balance of other nutrients that may be negatively affected, such as copper status. Another example of this is the critical role that magnesium plays in the synthesis and metabolism of vitamin D and parathyroid hormone [3].

The key considerations for nutritional balance are as follows:

- The microbiome: use of probiotics and foods in different gastrointestinal conditions
- Fiber: appropriate needs for different diagnoses
- Iodine: finding the right balance and removing antagonistic toxic halogens
- B vitamins: appropriate amounts and forms based on biochemical individuality
- Mineral balance: sodium, potassium, zinc, copper, magnesium, calcium iron
- Vitamin D status: associated requirement for magnesium
- Fat-soluble vitamins: individual requirements
- Omega-6 and Omega-3 fatty acids: ratios, adequate gamma-linolenic acid (GLA), and specialized proresolving mediators (SPM)
- Micronutrient and macronutrient ratios in different disease processes

8.2 The Microbiome

One of the core principles of Integrative and Functional Medicine Nutrition Therapy (IFMNT) is biochemical individuality, and recommendations for the feeding and care of individual microbiome are no exception. Although we are far from fully understanding the microbiome, certain research-guided patterns have begun to emerge. For instance, the conditions of obesity, type II diabetes, and nonalcoholic liver disease are associated with a higher abundance of the phylum Firmicutes compared with *Bacteroides* [4]. In certain disease states, we might find that overgrowth or subclinical bowel infections of normally occurring commensal bacteria, such as the *Klebsiella* microbes, may be associated with autoimmune diseases such as Sjogren's syndrome, ankylosing spondylitis, rheumatoid arthritis, or Crohn's disease [5].

Research suggests that changing the diet to one that is plant-based and high in fiber is a rapid, effective way to cause a beneficial change in our intestinal microbiome [6]. Conversely, for those with irritable bowel syndrome (IBS), small intestinal bacterial overgrowth (SIBO), or inflammatory bowel disease (IBD), this approach may not be appropriate. Foods high in certain types of fiber such as highly fermentable oligosaccharides, monosaccharides, disaccharides, and polyols (FODMAPs) may result in rapid gas production and discomfort for those with IBS and possibly those with SIBO or IBD [7]. Additionally, therapeutic diets for autoimmune disease may consist of grain-free, nut-free, dairy-free, egg-free, and legume-free diets which would make it almost impossible to successfully implement a solely plant-based diet. However, many plant foods can be incorporated into an autoimmune diet to promote a healthy microbiome. Diets need to be individualized in every circumstance.

Stool cultures may show that certain strains of beneficial bacteria, such as *Bifidobacterium*, are low, and a specific supplemental probiotic strain might be indicated. Recurrent infections such as *H. pylori* or *Strep pyogenes* may also indicate specific strains of probiotics to be used.

8.3 Fiber

Fiber intake is critical for gut ecology because of its role as fuel for the microbiome [8]. Many food sources of fiber contain a mix of both soluble and insoluble fiber. Soluble fiber becomes gel-like and is fermented by friendly bacteria in the colon to make short-chain fatty acids (SCFA). Insoluble fiber is not only indigestible but also important for stool bulking and better gut motility. Eating a wide variety of plant foods ensures a wide variety of the different types of fibers including pectin, gum, mucilage, cellulose, hemicellulose, lignin, and soluble fiber. The peels of fruits and vegetables are high in fiber, although all peels may not be edible or palatable.

Beneficial bacteria ferment soluble fiber, which produces short-chain fatty acids (SCFA) that, in turn, serve as a fuel source to colonocytes [8]. The fermentation of soluble dietary fiber by the microbiota produces SCFA that promote increased gut cellular proliferation and differentiation, lower intestinal pH which makes the gut more resistant to pathogens, and regulates inflammation. Fiber improves the health of the gut barrier by promoting tight junctions and increasing the production of mucins that play a role in forming mucus to protect the gut barrier [8].

Butyrate, a SCFA produced by fermentation of fiber, may decrease the risk of colon cancer by inducing apoptosis in tumor cells [9]. The 2011 Colorectal Cancer Report found evidence that for every 10 grams per day increase in fiber intake, there was a 10% decrease in colorectal cancer risk [9]. Fiber aids healthy elimination of toxins through the enterohepatic circulatory system with higher elevation of SCFAs while adding bulk to the stool to assist motility through the gut [8]. In general, consuming a variety of dietary fiber helps promote diversity of gut microbiota, which supports a more robust state of health [8]. A 2017 report of the gut microbiome of the Hadza hunter–gatherers of Tanzania who average 100–150 gm of fiber/day showed much greater microbiota diversity when compared with Americans who consume only about 15 grams of fiber per day [10]. Fiber intake from legumes, fruits, vegetables, and nuts had a protective effect against CVD events, and cereal fiber was associated with a lower risk of stroke and ischemic stroke [11]. Fiber intake is inversely associated with cardiovascular disease, body weight, type II diabetes, some cancers, and chronic diseases [12].

The recommended amount of fiber in the UK is 30 grams per day, while it is 14 grams for every 1000 calories in the United States [12]. The Institute of Medicine recommends 38 grams per day for men aged 50 and younger and 30 grams for males over 50. For women, the recommendation is 25 grams daily for those 50 and younger and 21 grams daily for those over 50 [9]. The amount of fiber recommended for children is the child's age plus 5 grams per day; an 8-year-old child, for instance, is recommended to consume 13 grams of fiber per day. However, Americans average 15 grams of fiber per day, which is very low, and only 3% of the population meets the recommendations for fiber intake [9, 12].

Most plant foods are a mix of soluble and insoluble fiber [13]. Some key sources of insoluble fiber include wheat bran, psyllium, quinoa, nuts–seeds, pine nuts, and flaxseed. Key sources of soluble fiber include beans, oats and oat bran, psyllium, barley, prunes, figs, pears, leafy greens, cauliflower, broccoli, flaxseed, acorn squash, and potatoes. Cozma-Petrut and colleagues suggest a new classification of fiber that includes solubility, fermentability, viscosity, and gel formation [13]. Examples of these categories include insoluble poorly fermented (wheat bran), soluble, nonviscous readily fermented (inulin), soluble, viscous gel-forming readily fermented (beta-glucans), soluble viscous–gel-forming low or non-fermentability (psyllium) [13].

Several studies suggest that the best tolerated and most effective fiber for IBS are those with low fermentability, such as psyllium [13]. For IBS, soluble fiber was found to be better tolerated and possibly helpful compared with insoluble fiber such as wheat bran, which may worsen symptoms [7]. For IBS, an intake of 20–30 grams per day of soluble viscous fibers with low rate of fermentation, such as psyllium and ground flax seeds, starting with a low dose and slowly increasing is recommended, at a rate of not more than 5 grams per week [7]. Psyllium husks and powder should always be mixed in plenty of fluid.

A novel concept regarding fiber intake for those with chronic idiopathic constipation is that these individuals may have worsening symptoms when consuming a high-fiber diet. Ho et al. [14] conducted a prospective longitudinal case study on subjects with chronic idiopathic constipation that showed marked improvement in constipation and bloating in subjects who consumed a low-fiber or no-fiber diet compared with those who stayed on a high-fiber diet. The authors point out that most individuals who visit medical practitioners for chronic constipation are already consuming a very high-fiber diet to self-treat their constipation [14]. Those who improve on a low-fiber diet may have bacteria that are fermenting the fiber which may contribute to bloating and constipation [14]. Fiber creates bulk in the stool that can make it more difficult to expel and can result in straining and fissures [14]. Fiber can slow peristalsis and result in a buildup of gas that becomes difficult to expel [14].

When adding fiber supplements to the diet, nutritionists need to use caution and start with low amounts and increase water intake so as not to cause constipation or a bezoar (intestinal blockage of a solid mass of indigestible material that accumulates in the digestive tract). In addition, if clients complain of severe constipation or of not having had a bowel movement for days or weeks, do not recommend fiber supplements until the constipation has resolved. It may be prudent to recommend they visit a physician to uncover the cause of the protracted constipation. In this author's clinical

experience, prunes, magnesium, vitamin C, flaxseed oil, or the herbal blend triphala, and aloe vera juice can be helpful in these cases, although caution is recommended for the use of aloe vera juice. At times, a physician-prescribed laxative is needed to clear a blockage. The nutritionist can follow this intervention with constipation prevention techniques (e.g., diet, 5-HTP, magnesium, etc.). In addition, referral to an integrative or naturopathic practitioner may help to manage lifelong constipation issues with other interventions such as homeopathics, herbals, acupuncture, and the like.

Notwithstanding all the benefits of fiber, the nutritionist may find it challenging to help patients consume a wide variety of fiber when certain gastrointestinal conditions exist. Judicious use of different fibers will be required for different gastrointestinal disease states and symptomatology. Determining the cause of a person's distress may be helpful in determining which type of fibers will be tolerated. An example is someone with severe IBS. Certain fermentable fiber products may worsen the symptoms. Instead of improving the person's health, these products may cause increased distress and worsen their constipation or diarrhea. Those with celiac disease (CD) might be made worse with oat fiber and certainly with wheat bran. Standard high-fiber foods often recommended such as beans, oats, apples, pears, plums, cashews, and pistachios might worsen constipation in someone with IBS, SIBO, or aggravate cases of IBD. In addition, healthy high-fiber seeds such as chia seeds, hemp seeds, and flax seeds might be damaging to sensitive individuals. Being familiar with FODMAPs, SIBO diets, the specific carbohydrate diet, and a low-residue diet is essential in helping patients with certain GI conditions to recover. Combing the market for suitable fiber supplements can be an arduous task but highly recommended, as one size does not fit all.

In summary, dietary fiber is a critical component to maintaining balance and diversity in gut ecology. Fiber can help normalize gut transit time, promote mucus production, and strengthen the gut barrier. Promoting the proper intake of fiber and water is crucial to improving the health of our clients. For those with IBS or chronic constipation, instead of using highly fermentable fiber grains, flax seeds, chia seeds, or fermentable fiber supplements, clinicians may simply want to recommend a diet that uses FODMAP-compliant fruits, vegetables, and increasing water intake. For these individuals, adding *Bifidobacter* probiotic supplements with the fiber may also be essential. If psyllium is to be added, start with very low doses; this author recommends 1–2 grams/day to start and slowly build up depending on individual tolerance. The herbal blend called triphala, as well as supplemental magnesium citrate, can be helpful with chronic constipation.

8.4 Iodine

Iodine is an essential element needed for thyroid hormone synthesis and fetal neurodevelopment [15]. The World Health Organization (WHO) and the US Institutes of Medicine recommend 90–150 mcg/day of iodine for the general population, 220–250 mcg/day during pregnancy, and 250–290 mcg/day of iodine during lactation [15]. The WHO uses median spot urinary iodine concentrations of 100 mcg/L to represent an intake of 150 mcg/day and 100–190 mcg/L per day to define adequate intake for a nonpregnant population [15]. Excessive iodine intake is classified by the WHO as the median urinary iodine excretion >300 mcg/L for general population and >500 mcg/L for pregnant women [16].

To assess iodine status, a clinician may use clinical manifestations such as thyroid size, combined with detailed history focused on the dietary iodine intake and a history of frequent or current infection, and laboratory testing for serum thyroglobulin, thyroid-stimulating hormone (TSH), and urinary iodine [15]. Urinary iodine reflects recent iodine intake within days, whereas thyroglobulin represents iodine intake over a period of months, and thyroid size assessment represents iodine intake for a period of years [15]. Either spot urine or 24-hour urine collection iodine testing may be used. Spot urinary iodine is more useful for assessing populations rather than the individual patient, as anything less than 10 urine samples in an individual is considered misleading due to diurnal variations [16]. Urine iodine levels also vary greatly in and between individuals based on the amount of iodine consumed in a day and the level of fluids ingested by the individual [15]. Expressing the ratio of urinary iodine to creatinine may be especially useful when estimating 24-hour urinary iodine [15].

Those at risk with iodine-deficient diets include vegans and people who avoid dairy or iodized salt, as well as athletes who experience excessive sweating [15]. Alternatively, people who consume kelp may have excessive iodine intakes [15]. Goiter is thought to be an adaptation to chronic iodine deficiency as low iodine intake leads to reduced thyroid hormone production, which stimulates TSH production from the pituitary gland. Goiter results as increased TSH increases iodine uptake, which stimulates thyroid growth [15]. In adults, the thyroid may develop nodules as it enlarges [15]. For those with overt hypothyroidism due to iodine deficiency, Niwattisaiwong et al. recommend initiating levothyroxine treatment along with iodine supplementation by using iodized salt or a multivitamin containing approximately 150 mcg of iodine [15]. When urine iodine has normalized and goiter has decreased, consider decreasing the thyroid treatment, but reassessing thyroid status in 4–6 weeks after stopping levothyroxine [15]. While mild gestational iodine deficiency does not result in cretinism (severe mental retardation and other neurologic or physical defects), children born to mothers with mild gestational iodine deficiency were found to have reductions in spelling, grammar, and English literacy performance [15].

In the recent past, high-dose supplemental iodine between 12 mg and 50 mg (12,000 mcg– 50,000 mcg) was a common recommendation in the integrative and functional medicine community for preventing breast cancer and helping with subclinical or overt hypothyroidism. While adequate amounts of iodine are required for healthy thyroid function, a need for caution exists if using supplemental iodine. The American

Thyroid Association (ATA) recently released a statement advising against the use of >500 mcg of iodine daily through dietary supplements [16]. Excessive amounts of iodine can be an environmental factor linked to the development of autoimmune thyroiditis and can cause hypothyroidism, hyperthyroidism, cancers, and autoimmune thyroid disease [17]. This can especially be a concern for autoimmune-prone individuals who are at risk of developing thyroid autoantibodies [17]. Iodine causes cytokine and chemokine-mediated lymphocyte infiltration in autoimmune-prone individuals, which is a key element in the production of thyroid autoantibodies [17]. Excess iodine is also thought to produce oxidative stress-related injury to thyrocytes, and active lipid peroxidation can occur after high-dose iodine administration [17].

Excessive iodine, an example of poor nutritional balance, can easily occur and is becoming a more common concern due to high levels of salt iodization, iodine in supplements, and regular consumption of iodine-rich foods [17]. Iodine toxicity has been reported due to overconsumption of seaweed in Asian countries [17]. Drinking water can also be a source of iodine excess in places such as Somalia, Saharawi, and Europe and can occur from the use of water purification systems that contain iodine [17]. In Western countries, dairy can be a source of excessive iodine from the animal feed and equipment-cleaning products used in the dairy industry [17]. Iodized salt may contain excessive or deficient amounts of iodine as diligent monitoring of iodine levels in salt does not always occur [17]. Multivitamin supplements testing in the United States had ranges for iodine between 11 and 610 mcg, and 15 brands had higher iodine levels than what was listed on the label [17]. Pharmaceutical products are another source of excessive iodine as Amiodarone contains 37% iodine; one tablet can contain several hundred times the recommended dose [17]. Contrast agents used for diagnostic radiology can contain hundreds of thousands of times the recommended daily amounts for iodine in one single dose. Transdermal antiseptic cleaners can also be a source of excess iodine for patients and healthcare workers [17]. It can take more than 1 month for the iodine levels in the body to normalize following exposure [17] (See Table 8.1)

To protect thyroid health, one lifestyle recommendation integrative and functional clinicians make is to limit exposure to the halogens consisting of fluoride, chlorine, and bromine. Iodine is a halogen as well, and excessive exposure to fluoride, chlorine, and bromine may result in the thyroid absorbing and storing these halogens, and thus displacing iodine. Halogens have the potential to interfere with the production of thyroid hormone, iodine metabolism, and may contribute to hypothyroidism or thyroid hormone derangement. For example, excessive ingestion of fluoride, even in the presence of adequate dietary iodine intake, may induce thyroid disturbances by interfering with enzymes such as deiodinases that are required for metabolizing thyroxine into its derivative forms [19]. Fluoride may also interfere with iodide transport and displace iodide resulting in accumulation in the thyroid [19]. Halogens are found in flame retardants, dioxins, pesticides, polychlorinated biphenyls, and fluoride. Chlorine is present in swimming pools and chlorinated drinking water [20].

Table 8.1 Tolerable upper intake levels for chronic iodine ingestion

Age	Male	Female	Pregnancy	Lactation
Birth to 1 year	200 mcg	200 mcg		
1–3 years	300 mcg	300 mcg		
9–13	600 mcg	600 mcg		
14–18	900 mcg	900 mcg	900 mcg	900 mcg
≥19	1100 mcg	1100 mcg	1100 mcg	1100 mcg

Based on data from Institute of Medicine (US) Panel on Micronutrients [18]
Note: The American Thyroid Association recently advised against consuming >500 mcg of iodine daily in supplements [16]

Current recommendations point to iodine supplementation between 300 and 500 mcg per day with diet and lifestyle changes to support healthy thyroid function. If the patient has autoimmune thyroiditis, it is best to limit iodine to iodized salt and dietary intake and steer clear of supplemental iodine. Some autoimmune patients seem to do better eliminating iodized salt, but every patient is different, and individual needs should be assessed.

8.5 B Vitamins

The concept of nutritional balance is important with dosing of B vitamin supplements. The B vitamins consist of eight water-soluble vitamins interacting together as coenzymes for a variety of catabolic and anabolic enzyme reactions [21]. Collectively, B vitamins have effects in proper brain function, energy production, DNA and RNA synthesis and repair, genomic and non-genomic methylation, and the synthesis of numerous neurochemicals and signaling molecules [21]. Although water-soluble and generally regarded as nontoxic, over-supplementation of a complex of B vitamins or isolated B vitamins such as B6 or folate is a concern. Conversely, underdosing by adhering strictly to RDA levels for certain B vitamins may leave some portions of the population at risk for insufficiency [21] (See Table 8.2).

Homocysteine, a potentially toxic amino acid, is thought to accumulate when vitamins B12, folate, B6, and/or trimethylglycine (TMG) are insufficient. Elevated homocysteine is theorized to increase oxidative stress, inhibit methylation reactions, increase damage to DNA and dysregulation of its repair, promote atherosclerosis [28], and direct and indirect neurotoxicity, leading to cell death and apoptosis [21]. These processes are thought to lead to the detrimental health conditions seen with elevated homocysteine including accumula-

Table 8.2 Tolerable upper limits of B vitamins

B Vitamin	RDA		Upper limit	Additional comments
B1 thiamine	*RDA for adults* [17]		Not established as no adverse effects have been found with daily doses of 50 mg [22]	Common dose of 50–100 mg for adults unless under special medical conditions exist such as alcoholism, malabsorption, the elderly, HIV/AIDS, or after bariatric surgery [22].
	Male	1.2 mg		
	Females	1.1 mg		
	Pregnancy and lactation	1.4 mg		
B2 riboflavin	Adults 19–50 years [23]		Studies have not shown adverse effects from high riboflavin intakes of 400 mg/day and there is no established UL [23]	Essential component of the two coenzymes FMN and FAD that play major roles in energy production, cellular function, growth and development, and metabolism of fats, drugs, and steroids [23]. FAD is required for the conversion of tryptophan to niacin [23]. FMN is required for the conversion of vitamin B6 to coenzyme pyridoxal 5′-phosphate [23]. Also used in the metabolism of homocysteine. Clinically it may be helpful in higher doses with prevention of migraine headaches [24]. People at risk for deficiency include vegetarians, athletes, pregnant and lactating women and their infants, vegan and dairy-free diet followers, infantile Brown–Vialetto–Van Laere syndrome [23].
	Males	1.3 mg		
	Females	1.1 mg		
	Pregnancy	1.4 mg		
	Lactation	1.6 mg		
B3 niacin	RDA for adults [25]: 16 mg males 14 mg females 18 mg pregnancy 17 mg lactation		35 mg [25]	Temporary flushing of the skin may occur at doses of 100 mg [21]. Nausea, vomiting, diarrhea, and very rarely liver damage have occurred at extended doses of 1 gram of more [21]. Doses of up to 250 mg have been used in Parkinson's disease [21].
B5 pantothenic acid	Adequate intake for adults [25]: 5 mg 6 mg pregnant 7 mg lactation		Not established [25]	Essential coenzyme in the mitochondria for formation of adenosine triphosphate (ATP) along with thiamine, riboflavin and niacin [21].
B6 pyridoxine (pyridoxal-5′-phosphate)	RDA for adults [25]: 1.3 mg 1.7 mg 51+ years 1.9 mg pregnancy 2.0 mg lactation		100 mg [25]	50–100 mg [16]. Essential in the metabolism of homocysteine. Doses over 100 mg have been known to cause neurosensory issues [21].
B9 Folate	RDA for adults [25]: 400 mcg 600 mcg pregnancy 500 mcg lactation		1000 mcg [25]	1000 mcg is the daily upper limit; however, 200–400 mcg is often recommended as research is unclear about supplemental folic acid and cancer [21]. Exceptions include the use of certain medications and higher levels than the upper limit may be indicated in some cases of high homocysteine [21]. High doses of folate can exacerbate the effects of B12 deficiency [21]. Folate is essential in the metabolism of homocysteine [24].
B12	RDA for adults [25]: 2.4 mcg 2.6 mcg pregnancy 2.8 mcg lactation		Not established [25]	Dependent on the individual physiological needs and conditions involving absorption [24]. Essential in the metabolism of homocysteine.
Inositol	No RDA set		Not established	Inositol can be synthesized in the body from glucose. Found in the germ and bran of grains, beans, nuts, seeds, and citrus fruit [26].
Biotin	Adequate intake for adults [25]: 30 mcg 35 mcg lactation		Not established [25]	Biotin, thiamine, and B12 interrelate in the citric acid cycle [16]. Biotin can be deficient genetically susceptible individuals or with dysbiosis. Biotin is formed by gut microbiota [27].

tion of beta-amyloid, hyper-phosphorylation of tau, brain tissue atrophy, compromised cerebrovascular circulation, cardiovascular disease, and compromised cognitive function and dementia [21]. Elevated plasma homocysteine levels can be due to renal insufficiency, deficiencies of folate, vitamin B12, vitamin B6 and vitamin B2 [29]. Plasma homocysteine levels were categorized by the 2009 US National Academy of Clinical Biochemistry Laboratory Medicine Practice Guidelines on Emerging Biomarkers of Cardiovascular Disease and Stroke as (umol/L): desirable <10, intermediate

>10 to <15, high >15, very high >30 [29]. For biomarkers for B vitamin assessment, see Table 8.3.

Elevated homocysteine and low levels of vitamins B12, B6, and folate have also been associated with bone loss and structural deterioration of bone tissue [35]. Deficiency of vitamin B12 is associated with lower blood levels of osteocalcin and alkaline phosphatase and may point to the activity of osteoblasts and bone metabolism being affected by vitamin B12 status [35].

While it is pertinent to address elevated homocysteine levels, the homocysteine hypothesis has resulted in limited B-vitamin research in other conditions with nutritional supplementation research focused mainly on folic acid and vitamin B12, only occasionally including vitamin B6 [3]. This has resulted in virtually ignoring the importance and interconnectivity of the role of the entire spectrum of B vitamins as essential in maintaining optimal physiological and neurological function [21].

Deficiency of even one B vitamin will negatively affect the ability to generate energy in the cell [21]. For example, the status of folate, B6, and B12 is dependent on levels of flavoproteins derived from riboflavin. Riboflavin is also essential to homocysteine metabolism [21]. Niacin, vitamin B3, serves as a necessary cofactor in the folate–tetrahydrobiopterin and methionine cycles [21]. Prolonged elevated folate status is associated with protected cognitive function only in those with normal B12 status, whereas high folate status exacerbated the detrimental effects of low B12 status [21]. Supplementation with folic acid also contributed to riboflavin deficiency in participants in one study [21].

The active forms of thiamine, riboflavin, niacin, and pantothenic acid are essential coenzymes in the mitochondria to

8

Table 8.3 Biomarkers to assess B vitamin status

B1	B2	B3	B6	Folate	B12
Whole blood thiamine pyrophosphate (TPP) available at labcorp. NL 66.5–200 nmol/L. Retrieved from ► https://www.labcorp.com/test-menu/36661/vitamin-bsub1-sub-whole-blood# on 2/17/2019. Urinary amino acids test or organic acids test can also be helpful	Riboflavin status is not routinely measured. Please refer to Riboflavin Fact Sheet for Health Professionals for more information [23]. Urinary organic acids test can be helpful	Most reliable: urinary excretion of niacin's two major methylated metabolites, N1-methyl-nicotinamide and N1-methyl-2-pyridone-5-carboxamide [30]. Levels in adults: Normal niacin status is >17.5 micromol/day of these two metabolites [30]. Low niacin status: Excretion rates between 5.8 and 17.5 micromol/day [30]. Deficient niacin status: urinary-excretion rates are less than 5.8 micromol/day [30]	Direct measurement: plasma pyridoxal 5'phosphate (P5P) >20 nmol/L [31]. This is affected by inflammation markers and albumin concentration [32]. Functional biomarkers may be better assessed by integrative testing	RBC folate is considered to be the most robust marker for long-term folate status. RBC folate for populations should be around 1000–1300 nmol/L. Woolf et al. used >140 ng/mL [31]. WHO recommends <906 nmol/L (>400 µg/L) in women of reproductive age to prevent neural tube defects [29]. Evaluate homocysteine and MMA. If homocysteine is high and MMA is normal, this phenomenon may reflect a folate deficiency [33]. Urinary FIGLU normal: not detected. Elevated levels can represent folate deficiency [34]. This case can be assessed through organic acids testing	Serum B 12 marker. Subclinical deficiency: <200 pmol/L. Low is 150–249 pmol/L. Acute deficiency is <149 pmol/L. This marker has limited diagnostic ability. Serum B12 does not represent cellular B12 levels [33]. Severe B12 deficiency has been documented with normal or high serum levels of B12 [33]. Plasma homocysteine is high at >13 µmol/L, can be used along with the most specific test for functional B12 deficiency which is elevated serum methylmalonic acid at >260–350 nmol/L, (118 pmol/L), or 0.80 µmol/L [33]. Reduced kidney function may affect the clearance of both homocysteine and MMA, thus resulting in higher levels. Another marker to consider in these cases is holo-transcobalamin (holo-TC) [33] Normal holo-TC level is 20–125 pmol/L. Below 20 pmol/L would be correlate with B12 deficiency [33]

Note: Iron deficiency should always be taken into account when assessing folate and B12 status. Iron deficiency causes microcytosis, whereas anemia of folate and B12 can cause macrocytosis [33]. Iron-deficiency anemia can mask macrocytosis and megaloblastic anemia from B12 [33].

make adenosine triphosphate (ATP), the cell's energy currency. Acetyl CoA provides the main substrate for this cycle and relies on pantothenic acid [21]. Thiamine, biotin, and B12 also interrelate in the citric acid cycle and electron transport chain. B vitamins have a fundamental impact on brain function and are actively transported across the blood–brain barrier with the concentration of methyltetrahydrofolate, biotin, and pantothenic acid found in the brain at levels much higher than plasma [21]. B vitamins can generally be consumed in amounts much higher than the RDA and may be necessary for optimal health. To date, only vitamins B6, B12, and folate have an established upper daily limit.

8.5.1 Thiamine (Vitamin B1)

Thiamine plays a role in the synthesis of fatty acids, steroids, nucleic acids, and aromatic acid precursors and in the synthesis of neurotransmitters and bioactive compounds essential for brain function [21]. Thiamine also plays a neuromodulatory role in the acetylcholine neurotransmitter system and can relieve fatigue associated with hypothyroidism [36]. Thiamine can be deficient in grain-free diets and depleted with high intake of alcohol [37]. In a study enrolling young women with adequate thiamine stores but given 50 mg of thiamine or placebo for 2 months, the thiamine-supplemented group reported improved mood as assessed by the Profile of Mood States. The thiamine-treated group also demonstrated improved attention evidenced by faster decision-making on reaction time tasks [21]. Thiamine plays a role in glucose metabolism. Between 17% and 79% of obese patients examined for bariatric surgery were found to be deficient in thiamine, and this may suggest a connection between thiamine status, blood sugar regulation, and obesity. In conditions of fatigue, neurological conditions, or hypothyroidism, higher supplemental doses of thiamine (50–100 mg) may be beneficial [19, 25]. Alcoholism and bariatric surgery will likely require far higher doses delivered under medical supervision.

8.5.2 Riboflavin (Vitamin B2)

Riboflavin is required for the synthesis of two flavoprotein coenzymes, FMN and FAD, which are rate-limiting factors in most cellular enzymatic processes [21]. The flavoproteins are required for the synthesis, conversion, and recycling of niacin, folate, B6, the synthesis of heme proteins, nitric oxide synthesis, P450 enzymes, and proteins involved in electron transfer and oxygen transport and storage. The flavoproteins are also involved in fatty acid metabolism in brain lipids, the absorption and utilization of iron, and the regulation of thyroid hormones. For many reasons, riboflavin deficiency would negatively impact brain function. Clinically, higher doses of riboflavin at 400 mg are helpful with preventing migraine headaches [24]. Recent randomized controlled trials have demonstrated that riboflavin may play a novel role as a modulator of blood pressure, specifically in individuals with the MTHFR 677TT genotype, and can reduce systolic BP by 5–13 mmHg in these genetically at-risk adults [38].

8.5.3 Niacin (Vitamin B3)

Niacin-derived nucleotides, such as nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), are critical for enzymes involved in every aspect of peripheral and brain cell function [21]. Niacin receptors are found in immune cells and adipose tissue as well. Niacin plays a role in neuromodulation of inflammatory cascades and antiatherogenic lipolysis in adipose tissue. People with Parkinson's disease are often low in niacin. One study found this population to benefit from 250 mg niacin supplementation, which resulted in attenuation of the disturbed sleep architecture associated with Parkinson's disease [21].

8.5.4 Pantothenic Acid (B5)

Pantothenic acid is required for the synthesis of coenzyme A (CoA). CoA plays a role in oxidative metabolism and contributes to the structure and function of the brain via its role in the synthesis of cholesterol, amino acids, phospholipids (PLs), and fatty acids. Through the action of CoA, pantothenic acid also helps with the synthesis of neurotransmitters and steroid hormones [21].

8.5.5 Vitamin B6

Vitamin B6 plays an essential role in the folate cycle and amino acid metabolism and is a rate-limiting cofactor in the synthesis of neurotransmitters including dopamine, serotonin, GABA, noradrenaline, and the hormone melatonin [21]. Neurotransmitter synthesis is especially sensitive to B6 deficiency. Even a mild deficiency can result in downregulation of GABA and serotonin synthesis. When GABA is unable to participate in its inhibitory role on neural activity, disordered sleep, behavior changes, cardiovascular function, and loss of hypothalamus–pituitary control of hormone secretion can result.

Low B6 status has been found in oral contraceptive users, smokers, and people with celiac disease, alcoholism, and diabetes [32]. B6 deficiency usually does not occur in isolation, but rather, with other B-vitamin deficiencies. Assessing B6 status can be difficult. Pyridoxal phosphate (PLP), the active form of B6, is often used to assess vitamin B6 by laboratory testing. PLP testing appears to be accurate in healthy individuals and has been found to reflect the vitamin B6 content in the liver and correlate with vitamin B6 dietary intake [32]. However, plasma PLP levels can be affected by albumin concentration, alkaline phosphatase activity, inflammation, and alcohol consumption [32]. Also of concern, low plasma PLP has been found with inflammation such as rheumatoid

arthritis, inflammatory bowel disease, cardiovascular disease, diabetes, deep vein thrombosis, and cancer [32]. Plasma PLP shows an inverse relationship with markers of inflammation such as C-reactive protein and other markers of acute phase reactants [32].

The activated form of B6, pyridoxal-5′-phosphate is downregulated during times of inflammation and therefore may contribute to dementia and cognitive decline due to the essential role it plays in brain glucose regulation, immune function, and gene transcription–expression [21]. Vitamin B6 can be over-supplemented and cause sensory neuropathy that is usually reversible. Evidence from case studies suggests that this can happen with as little as 100 mg per day [19]. Keeping the total amount of B6 to 50–100 mg per day is recommended [21]. If higher doses need to be used, consider this as a short-term intervention of 2–3 months, and a lower dose of around 50 mg should be recommended after this time period. There are, however, clinical trials that have used B6 doses as high as 750 mg over several years with no reports of neuropathy [21]. Individuals with certain single nucleotide polymorphisms in the CBS genes and MTHFR will have different requirements for vitamin B6. Please refer to ▶ Chap. 18 for this discussion.

8

8.5.6 Folate (Vitamin B9)

Folate and B12 are linked due to their complementary roles in the folate and methionine cycles [21]. If B12 is deficient, folate can become trapped as methyltetrahydrofolate, resulting in a functional folate deficiency [21]. Requirements for folate may also differ based on genetics. Either an actual or functional deficiency of folate may hamper DNA stability and repair as well as gene expression and transcription. This, in turn, affects neuronal differentiation and repair, which promotes hippocampal atrophy and demyelination. Ultimately, this compromises the integrity of membrane phospholipids resulting in the impaired action potential of the neuron [21].

A lack of folate may result in decreased synthesis of proteins and nucleotides required for DNA and RNA synthesis. This can have negative ramifications for rapidly dividing tissues, such as fetal development, and can lead to megaloblastic anemia and neuronal dysfunction [21]. Additionally, the folate cycle needs to function effectively to synthesize and recycle tetrahydrobiopterin, which is an essential cofactor for enzymes that convert amino acids to monoamine neurotransmitters such as serotonin, melatonin, dopamine, noradrenaline, adrenaline, and nitric oxide [21].

The upper daily limit for folic acid is set at 1000 mcg/day. This upper level is related to folate's ability to mask vitamin B12 deficiency, resulting in irreversible damage [21]. Detrimental effects of high doses of folic acid are related to high levels of unmetabolized folic acid on normal folate metabolism and immune function [21].

The use of folate comes with caveats. Individuals with MTHFR single nucleotide polymorphisms often require higher doses of folate [39]. Caution is advised in using high doses of folic acid in combination with antifolate medications, such as methotrexate, prescribed for conditions such as rheumatoid arthritis, psoriasis, cancer, bacterial infections, and malaria [21]. In addition, supplemental folate may confer protection against cancer at lower doses but may cause increased risk of cancer at higher doses, but there is no consensus on blood levels of folate that may cause harm.

As many patients turn to vitamins and supplements to enhance energy, relieve fatigue, or generally feel better, it is important to understand the connection between the B vitamins and psychiatric symptomatology. Vitamins B6, B8, and B12 have been shown not only to reduce psychiatric symptoms but also shorten the duration of illness [39]. However, when patients lack a specific genetic enzyme which converts folate–folic acid to its most usable form, L-methylfolate, the neuroprotective, and neuropsychiatric benefits are lost. L-methylfolate allows for the synthesis of the three major neurochemicals—serotonin, norepinephrine, and dopamine—across the blood–brain barrier [39]. Exploring the conversion of folate–folic acid into L-methylfolate and the various polymorphisms of the MTHFR gene while examining the B vitamins associated with the treatment of psychiatric symptoms allows integrative and functional practitioners to treat patients with the appropriate B vitamins [39]. For an in-depth analysis of how to assess folate status, please see ◘ Table 8.2 for biomarker assessment. For a detailed discussion, see Nutragenomics in ▶ Chap. 17.

8.5.7 Vitamin B12

Vitamin B12 is protective against neurological deterioration, and deficiency of B12 is associated with peripheral neuropathy, cognitive impairment, and neurodegenerative disease [33]. Causes of B12 deficiency are largely related to absorption in the GI tract, lack of intrinsic factor, or dietary deficiency such as with vegan diets [33]. Autoimmune pernicious anemia, intestinal surgery such as bariatric surgery, and chronic gastritis from *H. pylori* infections all decrease the release of intrinsic factor which can result in B12 malabsorption. Undiagnosed celiac disease can also result in malabsorption of B12 [33]. Some medications interfere with absorption and metabolism of B12, including metformin. Metformin decreases serum B12, but in some studies, it was shown to decrease plasma methylmalonic acid (MMA) and increase intracellular B12, although there are conflicting reports [33]. Metformin may alter B12 homeostasis and tissue distribution, but the clinical consequences remain to be determined. Proton pump inhibitors and other medications that reduce the production of hydrochloric acid are also associated with B12 deficiency [33]. B12 deficiency can be masked by folate supplementation and can cause severe neuropathy and neurodegeneration. An effective test for B12 sufficiency is MMA in blood or urine. Refer to ◘ Table 8.2 for assessment of B12 levels.

Doses of vitamin B12 that far exceed the RDA are commonly used in the integrative and functional nutrition realm. Anecdotally, nutrition practitioners have found that genetically susceptible individuals with catechol-O-methyltransferase (COMT) single nucleotide polymorphisms have a decreased ability to metabolize catecholamines, and supplementation with the methylcobalamin form of vitamin B12 may aggravate symptoms of anxiety and insomnia. Some of these individuals do better with hydroxocobalamin or adenosylcobalamin. To counter untoward effects when beginning B12 supplementation, start with a lower dose, such as 500 mcg, and slowly titrate dose upward.

The take-home message with B vitamins is to supplement all the B vitamins (not just one) because they work synergistically, even if the exact mechanisms has not been fully elucidated in research.

8.6 Fat-Soluble Vitamins

Fat-soluble vitamins are at risk of deficiency with certain states of malabsorption and malnutrition. When used in supplemental form, these vitamins need to stay in balance with each other, notably vitamin K1–K2 and vitamin D and vitamin D and vitamin A. Vitamin E is best provided in a natural full-spectrum combination as delta, beta, gamma, d-alpha tocopherols and the four tocotrienols, the way it is found in food.

8.6.1 Vitamin D and Vitamin K

One of the risks of using supplemental vitamin D is the increased gastrointestinal absorption of calcium that results in high serum levels of calcium and increased vascular calcification [40]. Theoretically, if vitamin D supplementation is balanced with supplementation of vitamin K1 and K2 in the forms of menaquinone-4 (MK 4) and menaquinone-7 (MK 7), this will decrease the likelihood of soft tissue calcification and of bone fracture [40]. In addition, a few vitamin K-dependent small proteins act to inhibit soft tissue calcification and include osteocalcin (bone Gla protein), matrix Gla protein (MGP), and possibly Gla-rich protein (GRP) [41]. The role of these proteins has been elucidated in studies monitoring the effects of treatment with oral anticoagulants that are known vitamin K antagonists (VKA).

With regard to VKA, all vitamin K-dependent calcification inhibitors will remain uncarboxylated and inactive [41]. Compared with controls, subjects taking anticoagulants had significantly higher calcification of arteries and the aortic valve [41]. Despite previous publications that reported vitamin K1 had no effect on bone mineral density, in a recent study, vitamin K1 deficiency was the strongest predictor of vertebral fractures and vascular calcification in chronic kidney disease. In postmenopausal women, 5 mg of vitamin K1 protected postmenopausal women from bone fractures, despite having no positive effect on bone mineral density [42]. Long-term, three-year supplementation with menaquinone (K2) of 180 mcg in 120 healthy postmenopausal women resulted in decreased arterial stiffness [40].

Vitamin K2 includes several different vitamers, of which MK7 is the most well-known. One study found that plasma concentrations of albumin and vitamin K1 were significant predictors of hip fracture in the general population, whereas MK7 was not [42]. To promote a decreased risk of bone fracture while protecting from vascular calcification, it is likely prudent to include both vitamin K1 and vitamin K2, specifically MK 4 and MK 7, when recommending calcium and vitamin D [42].

8.6.2 Vitamin A and Vitamin D

Vitamins A and D are important synergistic partners due to their shared binding of the nuclear retinoid X receptors (RXR), resulting in synergistic effects of one vitamin with the other. In nature, vitamins A and D are found together in balance such as in cod liver oil, egg yolk, and organ meats. Vitamins A and D function in many systems throughout the body beyond the eyes and bones. Furthermore, vitamins A and D are important as immune and hormone modulators as well as affecting structural forms such as bones, cell membranes, tissues, etc.

The effects of vitamins A and D supplementation on bone mineral density have been controversial. Observational studies have reported an association between higher serum retinol concentration and risk of bone fracture; another study reported that high retinol concentration in the presence of vitamin D deficiency can increase the risk of osteoporosis in menopausal women [42]; another recent study found that higher intake of vitamin A, when combined with sufficient intake of vitamin D, can promote increased bone density [43]. In a Korean population, a higher dietary vitamin A intake does not appear to negatively affect bone mineral density when 25 (OH) D levels are moderate at 50–75 nmol/L [43].

When assessing an individual's vitamins A and D status, it is beneficial to get a baseline of blood vitamin A retinol and vitamin D 25–OH, vitamin D1, 25-OH, and PTH, at minimum, to develop more targeted interventions and improve outcomes. If genomic information is available for vitamin D receptor and BCMO1 genes, genomic differences that influence the ability to establish balance between vitamin A and vitamin D might come to light. This highlights the fact that there are unique requirements for individuals to maintain nutrient balance.

Serum retinol and serum 25(OH)D can both be tested to ensure safe and adequate levels are maintained. Normal levels of serum vitamin A range from 50 to 200 mcg/dL or 1.75–6.98 micromol/L [6]. Interestingly, in nature, vitamins A and D are found together such as in egg yolk, liver, and butter. Overall, keeping the vitamin D level adequate appears to be protective to bones when supplementing vitamin A.

8.6.3 Tocopherols and Tocotrienols

Vitamin E is a family of fat-soluble antioxidants that mainly refers to alpha tocopherol, but naturally includes several tocopherols and tocotrienols [40]. Vegetable oils contain higher amounts of tocopherols, while tocotrienols are found in palm oil [44]. Both tocopherols and tocotrienols have four homologues consisting of alpha, beta, gamma, and delta [44]. Gamma-tocopherol is known mainly for its beneficial function in maintaining cardiovascular health, whereas the tocotrienols have shown more diverse application and protection against cancer, cardiovascular disease, neurodegeneration, oxidative stress, fertility, and immune regulation [44].

Tocotrienols exert different effects. Delta- and gamma-tocotrienols were more potent in cancer studies, while alpha-tocotrienols are more effective with neuroprotection. In a trial, subjects supplemented with gamma- and delta-tocotrienols showed a significant reduction in triglycerides and very low-density lipoprotein with no change in total cholesterol, LDL and HDL cholesterol, whereas the other homologues, alpha and gamma, did not show any effect on lipid profiles [44].

In preclinical cancer studies, tocotrienols have been shown to have antiproliferative, antiangiogenic, proapoptotic, and immune-enhancing properties [44]. The first clinical trial of tocotrienols involved a five-year, placebo-controlled, double-blinded study. Participants showed decreased number of deaths and incidence of recurrence in the tocotrienol group. Gamma-tocopherol showed increased apoptosis in a study on pancreatic ductal neoplasia.

Tocopherols and tocotrienols have neuroprotective properties and were shown to reduce glutamate toxicity, and subsequent damage to neurons and astrocytes and the use of vitamin E for the management of Alzheimer's disease is a topic of interest [45]. In a two-year study, daily supplementation of 400 mg of tocotrienol-rich fraction (TRF) resulted in statistically significant reduction in white matter lesions, compared with placebo group [44].

At this writing, there is no general consensus on recommendations for vitamin E intake as it is dependent on age, lifestyle, fat malabsorption, individual differences in vitamin E metabolism, and interaction with pharmaceuticals, such as blood thinners and statins [40]. Vitamin E may become a prooxidant when administered at high levels, but this effect may be mitigated by the coadministration of other antioxidants, such as vitamin C [40]. There is recent speculation that supplemental tocotrienol (T3) exerts more benefit than supplemental tocopherol and tocopherols should be solely obtained through food sources.

8.7 Minerals

8.7.1 Calcium and Magnesium

Calcium and magnesium are important nutrient partners that require balance, as elevation of one can cause suppression of the other. Integrative and functional medicine clinicians recommend supplementing calcium–magnesium at a ratio of 2:1 to 1:1. Supplemental calcium continues to be controversial as it may be associated with an increased risk for myocardial infarction, stroke, and cardiovascular mortality and an increased risk for kidney stones and soft tissue calcification [46] and more recently continues to be controversial as it may be associated with an increased risk for myocardial infarction, stroke, and cardiovascular mortality and an increased risk for kidney stones and soft tissue calcification [46]. There is growing evidence for the need for calcium supplementation to be in tandem and balanced with magnesium. Integrative and functional nutritionists often see clients with malabsorption, and part of the dietary intervention may include eliminating dairy products, often without recommending supplemental calcium or calcium-rich foods. This may have unintended harmful consequences (See Tables 8.4 and 8.5).

Using celiac disease (CD) as an example, calcium malabsorption and insufficient intakes of calcium may result in hypocalcemia, which produces a compensatory increase in serum levels of parathyroid hormone. This, in turn, leads to increased bone turnover and ultimately bone loss, with bone resorption being faster than new bone formation [47]. It is possible that the malabsorption of calcium is the main contributing factor to secondary hyperparathyroidism seen in CD [48, 49]. In addition, whenever parathyroid hormone is elevated, there is rapid conversion of 25 OH vitamin D to 1,

Table 8.4 High calcium foods to recommend to patients on dairy-free diets

1 cup okra, cooked	150 mg
1 cup spinach, cooked	350 mg
1 cup kale, cooked	94 mg
1 cup broccoli, raw	42 mg
1 cup collard greens, cooked	150 mg
1 cup turnip greens, boiled	190 mg
1 cup bok choy, raw	74 mg
3 oz canned sardines with bones	325 mg
3 oz canned salmon with bones	190 mg
½ cup firm tofu made with calcium sulfate	253 mg
1 cup calcium-fortified milk alternative	300 mg
Calcium-fortified juice	261 mg
½ cup soy beans and white beans	80–90 mg
Luna bar	350 mg
Power bar	300 mg
1 cup calcium-fortified cereal	250–300 mg
2 tablespoons of Tahini or sesame seeds	120–180 mg

Based on data from National Institutes for Health Calcium Fact Sheet for Health Professionals retrieved on 8/14/2017 from ► https://ods.od.nih.gov/factsheets/Calcium-HealthProfessional/

Table 8.5 Recommended daily allowances (RDAs) for calcium intake

Age	Male	Female	Pregnant	Lactating
0–6 months[a]	200 mg	200 mg		
7–12 months[a]	600 mg	600 mg		
1–3 years	700 mg	700 mg		
4–8 years	1000 mg	1000 mg		
9–13 years	1300 mg	1300 mg		
14–18 years	1300 mg	1300 mg	1300 mg	1300 mg
19–50 years	1000 mg	1000 mg	1000 mg	1000 mg
51–70 years	1200 g	1200 mg		

[a]AI (adequate intake) National Institutes for Health Calcium Fact Sheet for Health Professionals retrieved on 8/14/2017 from ► https://ods.od.nih.gov/factsheets/Calcium-HealthProfessional/

25 OH vitamin D (the active form of vitamin D) to enhance calcium absorption [48]. Clinically, you may see a low 25 OH and an elevated 1, 25 OH. Regarding CD, 75% of untreated adult CD patients with overt malabsorption, and about half of those with subclinical CD presenting with minimal symptoms or asymptomatic CD patients will have bone loss. In 2000, the British Society of Gastroenterology published guidelines for treating osteoporosis in CD that includes a daily calcium intake of 1500 mg and vitamin D supplementation [47]. Malabsorption of other micronutrients may also contribute to altered bone metabolism and increased pro-inflammatory cytokines that enhance osteoclastogenesis and bone resorption [49].

In cases where malabsorption is suspected, it may be prudent to request the patient have a parathyroid hormone test. It may be possible that secondary hyperparathyroidism may occur with low, normal, or high serum calcium levels. High serum calcium levels may be the result of long-term calcium malabsorption resulting in secondary hyperparathyroidism. Have clients work with a physician to see if they are a candidate for calcium and vitamin D supplementation. Clinically, it may be safe to assume that individuals at risk for calcium and vitamin D malabsorption include those with CD, inflammatory bowel disease, bariatric surgery (gastric bypass surgery) and other GI surgeries, eating disorders, and the presence of gastrointestinal pathogens [49]. Seeing a pattern of low normal serum protein, low normal albumin, low ferritin, or other markers of iron status, elevated MCV (suggesting deficiencies of folate and vitamin B12) and low normal serum calcium might suggest a pattern of malabsorption. Various medications, such as steroids, proton pump inhibitors, and loop diuretics, also increase the need for calcium supplementation [49]. The overarching recommendation is to dose calcium based on individual needs rather than blanket recommendations for the general population.

Magnesium is often left undiscussed in treating bone health and cardiovascular disease. Low magnesium status may lead to a greater risk of metabolic syndrome, type 2 diabetes, cardiovascular disease, skeletal disorders, chronic obstructive pulmonary disease, depression, decreased cognition, and vitamin D deficiency [3]. Magnesium plays a critical synergistic role in the synthesis and metabolism of parathyroid hormone (PTH), vitamin D-binding protein (VDBP), and three major enzymes that determine 25-OH vitamin D concentrations [3]. Magnesium deficiency leads to decreased levels of 1, 25 $(OH)_2$ D, the active form of vitamin D, and subsequent impaired PTH response [3]. Additionally, a specific form of vitamin D-resistant rickets that is magnesium-dependent exists and only responds to vitamin D therapy when magnesium is concurrently administered [3]. Readers will note other nutrients besides calcium, magnesium, and vitamin D that play a role in bone density include protein, vitamin K, zinc, copper, and boron.

Two small clinical studies on magnesium-deficient patients show that magnesium administered alone is not enough to raise vitamin D levels and that administration of vitamin D3 combined with magnesium infusion resulted in a substantial increase in both 25(OH)D and 1, 25 $(OH)_2$ compared with the infusion of magnesium alone. A recent NHANES study found that a high intake of magnesium was independently and significantly associated with a reduced risk of vitamin D deficiency [3]. Although more studies will elucidate the relationship between magnesium and vitamin D status, it may be prudent for clinicians to correct both vitamin D status and magnesium status concurrently. If clinicians experience vitamin D-resistant patients, the patient may be deficient in magnesium as well. Supplementing with vitamin D and calcium in the presence of suboptimal magnesium intake may be affecting health through interactions between the three nutrients that have not yet been fully explained [3].

Since 1977, the United States has increased both dietary calcium and magnesium intake, but dietary calcium intake has increased at a rate of 2–2.5 times that of dietary magnesium [3]. Some US studies have shown that since 2000, the calcium-to-magnesium ratio has increased ≥3 times and coincides with increasing rates of type 2 diabetes and colorectal cancer [3]. High dietary calcium-to-magnesium ratio has been proposed as an explanation for the striking variation in incidence of postmenopausal breast cancer associated with geographic location [50], the lowest calcium intakes being in Asia where the incidence of breast cancer is much lower compared to North America and northern Europe [50]. An imbalance of the calcium–magnesium intake may lead to irregularities in DNA repair, cell proliferation, differentiation, and carcinogenesis [50].

Reduced magnesium intake may be due to increased intake of refined and processed foods, softening of hard water, chronic alcohol ingestion, and gastrointestinal disorders causing malabsorption and certain medications. In addition, calcium supplementation may accentuate the problem of reduced magnesium intake [50]. Subclinical dietary magnesium deficiency was shown to increase calcium retention, and once calcium is high, magnesium absorption can be significantly depressed. Moderate alcohol consumption is

associated with breast cancer and alcohol exacerbates magnesium deficiency [50].

Higher self-reported dietary and supplemental magnesium intakes were associated with lower levels of coronary artery calcification, which is a sensitive, discriminating measure of subclinical cardiovascular disease [51]. Huang et al. found that consumption of moderate amount of calcium and an adequate amount of magnesium with maintenance of calcium-to-magnesium ratio of 2.0–2.5 are important for reducing cardiovascular risks in older patients with diabetes [52]. Individuals who consume 1000–1200 mg of calcium per day need to increase their magnesium intake to maintain the calcium-to-magnesium ratio of 2.0–2.5 [52].

Traditional advice is to maintain calcium-to-magnesium ratios for optimal health [3], and the authors of a 2007 colorectal neoplasia study suggested the optimal dietary calcium-to-magnesium ratio be <2.8. It is thought that calcium-to-magnesium ratios >2.6–2.8 can have detrimental health effects, and it has also been questioned if a calcium-to-magnesium ratio of <2.0 may also be detrimental [3]. More research is needed to establish a beneficial ratio.

8.7.2 Sodium-to-Potassium Ratio and Hypertension

The effect of sodium-to-potassium (Na–K) ratio on hypertension is perhaps more important than looking separately at the effect of individual sodium or potassium intake on hypertension. Inconsistencies have been found in observational studies around the world showing a relationship between high sodium intake and hypertension, as well as high Na–K ratios and hypertension [53]. The mechanisms of sodium and potassium on blood pressure are multiple. In salt-sensitive individuals, sodium intake results in sodium and water retention and extracellular volume expansion. The extracellular volume expansion results in release of substances that increase heart and blood vessel contraction and affect the renin–aldosterone system [53]. Potassium increases urinary sodium excretion, which lowers serum sodium levels, and is thought to induce vascular smooth muscle relaxation or widening of the blood vessels to lower blood pressure [53].

Potassium is an electrolyte needed for normal cellular function and is easily excreted by healthy functioning kidneys rather than stored in the body [54]. Therefore, humans need a constant supply of potassium through the diet. Adequate intake of fruits and vegetables is a major source of potassium [54]. The average potassium consumption is at 54% of the US recommended intake [54]. Low potassium intake is also correlated with central obesity and metabolic syndrome [54]. A caveat is high potassium intake which is contraindicated in renal disease because of poor excretion and potential for elevated levels.

Potassium supplementation has consistently been shown to lower blood pressure, and low dietary potassium is associated with an increased risk of developing hypertension [55]. The joint effect of high sodium and low potassium intakes may have a greater effect on hypertension than elevated sodium intakes or low potassium intakes alone [53]. In a Korean study by Park et al., dietary intake of both sodium and potassium was evaluated, and the authors showed that an increased ratio of sodium to potassium was correlated with increased prevalence of hypertension [53].

Study subjects who had a lower prevalence of hypertension had a Na–K ratio of 1.21:1, and with increased prevalence of hypertension, there was a Na–K ratio of 2.56:1 [56]. Additionally, blood pressure results had almost a linear dose response to increasing ratio of Na–K [53].The blood pressure lowering effects of potassium were greatest in those with the highest intake of sodium, and the ratio of Na–K had a greater effect on the risk of cardiovascular disease than sodium or potassium alone [53]. Recommending a diet high in fresh fruits and vegetables, including low-fat dairy products, and consuming a whole-food diet, is likely the most effective approach for lowering the Na–K ratio [53]. Caution is advised when looking at sodium-to-potassium ratios as great variability in sodium sensitivity exists between different ethnic groups [53].

8.7.3 Zinc and Copper

Zinc and copper are another example of nutrient partners that need to be metabolically balanced. Excessive elevation of either one can suppress the other, much like the relationships described above.

Zinc is used clinically in supplement form to facilitate wound healing; decrease skin inflammation; support immune function, tissue growth, and maintenance of thyroid function; promote GI tract healing; protect against such ocular diseases as macular degeneration; and promote testosterone balance. Zinc supplementation can induce copper deficiency that may result in serious neurological conditions, hematological abnormalities, and possibly thyroid abnormalities; therefore, zinc needs to be balanced with copper [57, 58]. High tissue–copper levels may be associated with inflammation and certain disease states, such as cancer. "The RDA recommendations for zinc and copper intake are in a ratio of 9:1 [59]". When working with medical conditions, it is important to measure a baseline blood test for both nutrients to determine if supplementation of either is needed. (See Table 8.6 Assessing zinc and copper status.)

Measuring the serum copper to zinc ratio is a helpful parameter in states of disease and inflammation. The normal plasma zinc to serum copper ratio in children and adults is 1:1 [64]. The increment of this ratio of the opposite (copper–zinc) above 2.0 in the elderly usually reflects an inflammatory response or decreased zinc status [65]. High serum copper to zinc ratio has been associated with cardiovascular death, malignancy, and all-cause mortality in the elderly [65]. During the acute phase of various diseases, systemic mechanisms decrease zinc and increase copper. Using the ratio of serum copper to zinc may be more predictive of inflamma-

Table 8.6 Summary of copper and zinc assessment

Copper reference ranges	Zinc reference ranges
Serum free copper: 1.6–2.4 μmol/L or 10–15 μg/dL [60] *Total copper*: 10–22 μmol/L or 63.7–140.12 μg/dL [60] *Serum ceruloplasmin*: 2.83–5.50 μmol/L or 18–35 μg/dL [60] <20 mg/dL ceruloplasmin signifies Wilson's disease along with Kayser–Fleischer rings [61]. Wilson's disease is a genetic defect in copper excretion. *24-hour urine copper*: 0.3–0.8 μmol or 20–50 μg [60] <40 mcg/day [61] >100 mcg/day occurs in Wilson's disease [61] *Liver copper*: 0.3–0.8 μmol/g of tissue or 20–50 μg/g of tissue [60]	*Normal serum zinc*: 60–120 μg/dl [62] *Plasma zinc is deficient if below*: 60 μg/dL [63] *Alkaline phosphatase (ALP) normal range*: 45–115 units/liter (U/L) [62] <45 U/L ALP indicates zinc and/or magnesium deficiency [62] * For reference in assessing low ALP, normal serum magnesium: 1.3–2.5 mEq/L [62]

tion than using other inflammatory biomarkers such as CRP and ESR [65]. Nutritional factors such as increased copper intake and decreased zinc intake are not thought to be the cause of an elevated copper-to-zinc ratio during states of inflammation, but rather, other systemic mechanisms may be the cause. Zinc is carried on albumin, and copper is carried on ceruloplasmin (Cp). Synthesis of these proteins and the regulation of serum copper and zinc occurs mainly at the hepatic level.

During oxidative stress, the albumin-bound zinc in the plasma decreases while labile zinc relocates to peripheral tissues [65]. This labile zinc induces the antioxidant metallothionein (MT). Infections and inflammatory conditions which induce oxidative stress cause copper–ceruloplasmin levels to rise. During inflammation and aging, the cytokines interleukin (IL) 6, IL-1 beta, tumor necrosis factor-alpha, and interferon gamma (IFN-gamma) are known to suppress the synthesis of albumin (i.e., bound to zinc) and increase the synthesis of ceruloplasmin. This mechanism may be protective in response to oxidative stress, infection, and low-grade inflammation. Impaired insulin action also decreases the synthesis of albumin, which may, in turn, decrease plasma levels of zinc.

Following inflammatory stimuli, zinc is redistributed from the plasma to the liver, thymus, and marrow. This may be a mechanism to restrict zinc from being used by invading pathogens, protect the liver and tissues from oxidative stress by producing MT, and manufacture lymphocytes to protect against invading pathogens [65]. Increased levels of copper in the serum may help the antimicrobial function of macrophages. Very low or undetectable levels of zinc are found in infected tissue, whereas copper accumulates at sites of infection where macrophages are present in high amounts [65].

Copper deficiency impairs oxidative phosphorylation, cellular antioxidant defense, collagen and elastin biosynthesis, production of several metalloenzymes such as copper–zinc superoxide dismutase, and affects levels of selenium-dependent glutathione peroxidase [64]. Copper deficiency impairs blood coagulation, has adverse effects on blood pressure and heart function, affects cholesterol and glucose regulation, contributes to neurodegeneration, causes anemia, affects cross-linking of connective tissue, and causes mineralization of the bone, ultimately leading to osteoporosis [66]. Copper deficiency results in optic neuropathy [67]. Anemia that is refractory to iron supplementation is a classic, well-documented sign of chronic copper deficiency [68]. One study in frail elderly men found decreased hematocrit and serum iron levels in subjects who had an elevated serum copper to zinc ratio [68]. Additional symptoms of copper deficiency include leukopenia, neutropenia, decreased superoxide dismutase, decreased ceruloplasmin, increased plasma cholesterol and LDL–HDL ratio, and abnormal cardiac function [64].

Copper intoxication rarely occurs in humans, as it is excreted in the bile [64]. However, elevated copper levels are associated with infections, inflammation, Wilson's disease, trauma, systemic lupus erythematosus (SLE), and autism [64]. Both zinc and molybdenum deficiency may be a risk factor for copper toxicity. Due to its role as a cofactor, copper toxicity has been associated with such neurological diseases as amyotrophic lateral sclerosis, Alzheimer's disease, and Creutzfeldt–Jakob disease [64]. Physiological factors independent of copper intake can affect copper levels. Plasma copper levels are higher in women than men due to estrogen [59]. Infection, inflammation, and estrogen levels increase plasma copper. Corticosteroid and adrenocorticotropic hormone lower copper concentrations.

Copper is bound to the protein ceruloplasmin that is regulated by homeostatic mechanisms [59]. High serum copper concentration with elevated copper-to-ceruloplasmin ratio is indicative of copper excess [59]. In Wilson's disease, a condition of copper excess, free copper is elevated, and ceruloplasmin is lowered [59]. Ceruloplasmin is an acute phase reactant and may be raised in response to hepatic inflammation, pregnancy, estrogen use, or infection [61]. Falsely low ceruloplasmin levels may occur with any protein deficiency state including nephrotic syndrome, malabsorption, protein-losing enteropathy, and malnutritions [61].

A review of methods of assessment of copper status in humans suggests that serum copper seems to be the most accurate biomarker to assess copper status in humans, reflecting changes in status in both depleted and replete individuals [69]. Measuring copper levels may be elusive, but low plasma or serum levels of copper indicate depletion. Hair and urinary copper are not useful indicators of copper status [59]. Total ceruloplasmin protein level is related to copper status, but deficiency reflects changes in highly depleted individuals only [69]. One of the first signs of copper deficiency is a drop in ceruloplasmin. Ceruloplasmin accounts for 90% of total plasma copper [70]. Ceruloplasmin and serum copper are

acute phase reactants and can rise in response to inflammation, even in states of copper deficiency [66].

The dosing range for copper in adults is 2–10 mg/day with monitoring of zinc status during supplementation [59]. In states of copper deficiency, typically 2 mg/day of copper will reverse the hematological abnormalities in the early stages [58].

8.7.4 Assessing Zinc Status

Symptoms of severe zinc deficiency include hypogonadism, dwarfism, growth-retarded infants and children, dermatitis, diarrhea, alopecia, and loss of appetite [64]. More moderate zinc deficiency can result in decreased immune function, increased mortality due to infections, and brain damage in a fetus when the pregnant mother is zinc deficient [64]. Zinc-repletion dosing ranges anywhere from 5 mg/day to 50 mg/day with monitoring of copper status during supplementation [59].

There is currently no specific sensitive biochemical or functional indicator of zinc status [71]. Accurate measures of plasma zinc are complicated by the body's homeostatic control of zinc levels and factors affecting zinc status that are unrelated to nutritional status [71]. Plasma zinc is bound to its carrier protein albumin; therefore, anything that alters albumin levels will alter plasma zinc levels [59]. There is no functional reserve of zinc in the body, and the body's zinc levels are maintained by conservation and tissue redistribution [71].

Cessation of growth in children is an example of severe zinc deficiency [71]. When dietary zinc intake is low, fecal zinc excretion may be reduced by 60%, coupled with increased intestinal zinc absorption. In mild zinc deficiency, plasma zinc can be maintained at the expense of zinc from other tissues [71]. Therefore, plasma zinc is not a reliable measurement of zinc intake or whole-body zinc status [71]. Plasma zinc levels in mildly zinc-deficient growth-retarded children who responded to zinc supplementation were not significantly different from normally developed children, before or after zinc supplementation [71].

Decreased plasma zinc levels may result from stress, infection, inflammation, use of estrogen, oral contraceptives, and corticosteroids. Plasma zinc levels are known to fall 15–20% after a meal [71]. Increased zinc levels may occur from fasting or red blood cell hemolysis [59]. A better alternative to plasma zinc levels might be red blood cell zinc levels, as RBCs contain zinc-dependent proteins. RBCs turn over every 120 days; hence, RBC zinc status would reflect whole-body zinc status over a longer period of time than plasma zinc and is not prone to recent changes in whole-body zinc status [59].

Zinc-containing enzymes are another possible marker for zinc status, and alkaline phosphatase has been studied as a biomarker for zinc status. In a study in Guatemalan children, low serum zinc was associated with low serum albumin and low serum alkaline phosphatase [72]. When assessing ALP, it is important to differentiate if low alkaline phosphatase is due to zinc or magnesium deficiency [62]. When zinc was repleted, the serum zinc increased, as did alkaline phosphatase. Other studies in Guatemalan children have shown an association between serum zinc and alkaline phosphatase [72]. However, it was noted in children and adolescents depending on age, serum alkaline phosphatase levels have a wide variation and therefore should be interpreted cautiously.

8.7.5 Copper-to-Zinc Ratio in Cancer

Functional medicine experience-based practice recommendation in serum copper-to-zinc ratio is 1:1 for optimal health, although this author could not find research to corroborate at this time. When serum copper-to-zinc ratio is being assessed during cancer treatment, serum zinc is used. Numerous studies have found an association between elevated copper-to-zinc ratio and disease severity. Inducing copper deficiency to prevent angiogenesis in cancer has been proposed as an adjunctive treatment for cancer [70]. Currently, it is uncertain if enough research exists to put this into clinical practice. A phase II trial of advanced kidney cancer looked at inducing copper deficiency by using TM, a novel antiangiogenic agent, to chelate copper, with the goal of lowering ceruloplasmin level to 5–15 mg/dl for 90 days [70]. This resulted in disease stabilization rather than a reduction in disease burden. The authors proposed that this may only be useful for a patient with minimal disease.

Diez et al. reported on the ratio of serum copper to zinc in diagnosis of lung cancer and found ratios of 2.34 ± 0.78 in the lung cancer cohort, 1.62 ± 0.23 in patients with benign pulmonary lesions, 1.43 ± 0.29 in patients with benign lung diseases, and 0.188 (not significant) in healthy subjects [73]. A cutoff value of Cu–Zn ratio of 1.72 resulted in sensitivity of 89%, specificity of 84%, positive predictive value of 7%, and negative predictive value of 92% between lung cancer patients and healthy subjects [73]. Lung cancer patients with pretreatment Cu–Zn concentrations equal to or above 2.25 had 24-month survival rates of less than 5%. By contrast, pretreatment Cu–Zn levels below 1.72 were associated with 24-month survival rate of 70% [73].

Functional medicine doctors working in oncology typically strive for a serum Cu–Zn ratio of 1.0, although this author could not find adequate studies supporting this ratio.

Serum Cu–Zn ratio should be interpreted cautiously in cases of suspected malignancy that are accompanied by infections, liver diseases, use of oral contraceptives, or other conditions known to affect copper.

8.8 Fatty Acids and Phospholipids

8.8.1 Fatty Acid and Phospholipid Balance

A balanced ratio of omega-6 to omega-3 fatty acids is important for overall health related to its impact on inflammation, immune balance, obesity, depression, and cardiovascular disease. See also ▶ Chaps. 10 and 11. Omega-6 and omega-3

fatty acids cannot interconvert into one another; they are metabolically and functionally distinct and have important, opposing physiological effects [74]. Alpha-Linolenic acid (omega-3) and linoleic acid (omega-6) are the two essential fatty acids that must be obtained through the diet; they cannot be endogenously formed by humans and other mammals due to a lack of enzymes for desaturation [74, 75].

The balance of omega-6 compared with omega-3 fatty acids influences the metabolic pathway of each of these fatty acids [76]. Omega-6 and omega-3 fatty acids produce different eicosanoid products that result in different effects on inflammation. The need for balance between the eicosanoid families is critical for metabolism involving inflammation, resolving inflammation, structural composition, hormones, and immune functions. The nutritionist should be aware of the balance of the eicosanoids, their downstream metabolites, and the functions of such prostaglandins as PG1, PG2, PG3, and specialized proresolving mediators (SPM).

In the past three decades, because of public health prescriptions for low-fat diets, the intake of overall fat in the Western diet has decreased. However, proinflammatory omega-6 fatty acid consumption has increased, while omega-3 fatty acid consumption has decreased [74]. The ratio of omega-6–omega-3, historically, was 1:1–4:1, and today it is reported to be around 20:1. This change in consumption correlates with the rising epidemic of obesity and inflammatory disorders [74]. Arachidonic acid (AA), an omega-6 fatty acid, is a critical fatty acid for cell membrane structure and resolution of inflammation as it promotes specialized SPM. However, when it is out of balance, excessive AA can become pro-inflammatory. As with all molecules and metabolites throughout metabolism, altered metabolic balance can promote dysfunction.

AA is used as a substrate to make eicosanoids such as prostaglandin E2 and leukotriene B4 [74]. These cytokines, when in excess, are pro-inflammatory and more potent mediators of thrombosis and inflammation than cytokines derived from omega-3 PUFAs. Eicosanoids from AA are biologically active in small amounts, and when present in large amounts, they contribute to the formation of thrombus and atheromas, allergic and inflammatory disorders, and proliferation of cells [74].

EPA and DHA, both omega-3 essential fats, suppress the production of proinflammatory cytokines IL-1B, Il-6, and TNF alpha [75]. EPA inhibits AA synthesis from linoleic acid and competes with AA for enzymatic conversion, resulting in reducing AA conversion to pro-inflammatory molecules [75]. The ingestion of fish or fish oil results in the EPA and DHA partially replacing omega-6 in the cell membranes of platelets, erythrocytes, neutrophils, monocytes, and liver cells [74]. In humans, the cerebral cortex, retina, testis, and sperm are particularly rich in DHA, and DHA is abundant in the brain's structural lipids [74].

During evolution, omega-3 fatty acids were found in almost all foods consumed including meat, fish, wild plants, nuts, and berries [74]. The dietary and agricultural changes over the last 100–150 years have resulted in less omega-3 available in foods and an increased risk for changing the physiological state of the body to a more inflammatory, atherogenic state. The balance of omega-6 to omega-3 can affect gene expression, prostaglandin, and leukotriene metabolism and interleukin-1 production [74]. Modern agriculture and aquaculture have changed the omega-3 fatty acid content for the worse in many foods by replacing them with omega-6 fats.

Depression is associated with low plasma phospholipid and erythrocyte levels of EPA and DHA [75]. It is possible that omega-3 fatty acids aid in mitigating depression by decreasing inflammation systemically. Evidence points to utilizing supplemental omega-3 fatty acids for therapeutic intervention of depression as a monotherapy or in addition to antidepressant medications, although results have been mixed [75]. It has yet to be determined what blood levels of EPA and DHA might be associated with improvement in depression. Therapeutic levels of omega-3 depend on diet, genetic variation in omega-3 fatty acid metabolism, and the rate of absorption and incorporation into biologic systems [75]. In both short- and long-term studies, a fixed daily dose of omega-3 results in a large variation of individual omega-3 blood levels, possibly due to genetic polymorphisms and dietary intake. In a study on supplemental omega-3 fatty acids and depression, researchers found that participants whose depression remitted had higher baseline omega-3 levels than those whose depression did not go into remission [75].

RBC levels are less sensitive to recent intake of omega-3 compared with plasma levels and may provide a more reliable estimate of omega-3 levels over time [75]. A level of 5–6% of omega-3 in RBC may be a reasonable target to provide a therapeutic level. However, those who experienced remission of depression had levels of omega-3 in RBC at 8% with the highest probability of remission at 9–10% [75]. This finding is similar to results of a review on omega-3s to improve cardiovascular outcomes [75]. Overall, looking at individual RBC levels to obtain therapeutic efficacy might be a better way to dose supplemental omega-3 than providing a fixed dose for everyone.

Omega-3 fatty acid-enriched diets improve inflammatory status of metabolic dysfunction and reduction in adipose tissue if kept in balance with other essential fats [76]. Supplementation with omega-3 fatty acids and certain doses of omega −6 fatty acids was shown to help with decreasing body fat mass and hip circumference loss [76]. Dietary interventions optimizing the ratio of omega-6 to omega-3 have shown significant reduction in low-density cholesterol as well. Omega-6 versus omega-3 essential fats have different influences on body fat mass through mechanisms of adipogenesis, lipid homeostasis, brain–gut–adipose tissue axis, and systemic inflammation [74]. In summary, lowering omega-6 and increasing omega-3 may decrease the risk for weight gain and associated inflammation.

Testing RBC fatty acid profiles is helpful to clinicians when assessing fatty acid balance and is important because AA and DHA both have critical but different biological func-

tions. There may be instances where omega-3 fatty acid levels are too high compared with levels of arachidonic acid (AA), which may have untoward consequences. The eicosanoids produced from AA are important for immunity and immune response and serve as mediators and regulators of inflammation [77]. AA is critical for infant growth, brain development, and health. Too much DHA may suppress benefits provided by AA [77]. DHA controls signaling membranes in the photoreceptor, brain, and nervous system, whereas AA has a role in the vasculature and certain aspects of immunity [77]. Animal studies have provided evidence that both preformed DHA and AA are required for optimal cognitive function [77]. More about omega-3 dominance is found in the section on gamma-linolenic acid.

8.8.2 Gamma-Linolenic Acid

Gamma-linolenic acid (GLA) and its downstream metabolite di-homo-gamma-linolenic acid (DGLA) are two omega-6 fatty acids important to any discussion of fatty acids (please see ▶ Chaps. 10 and 11). They are often grouped into the "too much omega-6 statements" without addressing their critical importance in nutritional therapy. GLA is not present in the human diet and is formed from the essential fatty acid cis-linoleic acid [78]. It is often supplemented in the form of borage oil, evening primrose oil (EPO), or black currant seed oil. As a metabolite of the essential fatty acid linoleic acid (LA), GLA, in turn, produces DGLA. DGLA is available as a substrate to produce AA or be directed to form the prostaglandin 1 series (PG1) metabolites. The balance needed between the prostaglandin groups is another critical consideration when assessing an individual's fatty acid balance. For example, autoimmune and skin conditions are dependent on adequate PG1 molecules. Most of the PGs, TXs, and LTs are proinflammatory. AA products generally enhance inflammation as the precursor of 2-series PGs and thromboxanes (TXs) and 4-series leukotrienes (LTs) [79]. Therefore, the balance of AA to DGLA in the body may be a critical factor in regulating inflammatory processes [78].

GLA metabolism in humans is complex as all the cellular compartments metabolize GLA differently [79]. This difference is due to differential expression of PUFA-metabolizing enzymes. GLA supplementation can lead to increased DGLA levels in certain inflammatory cells but can increase both DGLA and AA in circulating lipids [79]. The impact of AA accumulation in the body remains controversial. When GLA is given with omega-3 fatty acids, the conversion of DGLA (from GLA) to AA is inhibited, and the accumulation of serum AA appears to be prevented [79].

Inflammation is the immune system's response to infection and injury and facilitates the removal of the cause of the inflammation (the offending agent) and the restoration of tissue structures and physiological function [80]. Inflammatory prostaglandins derived from AA play a key role in necessary inflammation. Therefore, our goal is not to eliminate inflammation but, rather, keep it in check. Persistent and dysfunctional inflammation may promote cancer, cardiovascular disease, autoimmune disease, and the loss of organ function [80]. The nutritional balance between GLA, DGLA, and AA and their metabolites may be key to maintaining a healthy balance of inflammation in the body.

Deficiency of fatty acids is often due to dietary insufficiency, but excessive supplementation of flax or fish oils leads to omega-3 fatty acid dominance [81]. Potential laboratory findings will reveal high omega-3 fatty acids with low AA fatty acids and elevated EPA–DGLA ratio as well as depressed AA–EPA ratios. This imbalance will produce a lowering of class 2 eicosanoid signals, which may lead to blunting of immune responses [81]. Supplementing omega-3 fatty acids in an individual with a deficiency of n-6 fatty acids can further exacerbate clinical outcomes by competing for desaturase enzymes. Adding GLA-rich evening primrose oil may improve the clinical outcome in these individuals [81]. A diet low in LA can be corrected by supplementing with LA-rich oils and/or correcting for malabsorption.

Another risk of omega-3-dominant conditions is lipid peroxidation of cell membranes and increased risk of oxidative damage in the body that may give way to serious health conditions, including heart and neurological diseases. In general, it is recommended to supplement with antioxidant nutrients when using omega-3 fatty acids to protect against lipid peroxidation and monitor fatty acid profiles and antioxidant nutrients [81].

To prevent an imbalance in fatty acids, consider supplementing the full range. When GLA, DGLA, EPA, and DHA are given together, the overproduction of pro-inflammatory cytokines IL-6 and TNFα is suppressed [78]. The combination of GLA, EPA, and DHA in supplemental form would likely induce a powerful combination of anti-inflammatory and necessary inflammatory metabolites [79]. Common genetic and epigenetic variations affect the rate of conversion of long-chain PUFAs and their metabolites and are strongly related to ethnicity, suggesting that "one size fits all" dietary and supplement recommendations for fatty acids may not be appropriate, with laboratory testing critical [79].

8.8.3 Conjugated Linoleic Acid

Conjugated linoleic acid (CLA) is another fatty acid that may have anti-inflammatory and anti-cancer benefits. CLAs are a series of isomers of LA and chemically do not belong to the omega-6 family; however, they can originate from the endogenous biohydrogenation of LA by gastrointestinal tract bacteria [82]. CLAs have demonstrated a benefit in inflammatory bowel disease (IBD) and colon cancer and may serve as an agonist for peroxisome proliferator-activated receptor gamma (PPARγ) [83]. PPARs are nuclear receptors for endogenous lipid molecules such as prostaglandins or hydroxyl-containing PUFAs [83]. Their main biological function is to sense intracellular nutrient concentrations and regulate gene expression involved in maintaining metabolic and tissue homeostasis. When CLA is used in conjunction

with omega-3 fatty acids, it may prevent or ameliorate IBD in animal models [83]. In addition to activating PPAR γ, CLA can also modulate the production of AA metabolites, which may reduce the production of inflammatory lipid mediators. Several CLA isomers are found naturally in milk, cheese, and ruminant products [83]. Grass-fed beef and fatty milk products from grass-fed beef are good dietary sources of CLA.

8.8.4 Phospholipids

Any discussion on fatty acids must include a discussion on the importance of phospholipids. Phospholipids (PLs) are amphiphilic lipids (containing both hydrophilic and hydrophobic properties) found in all animal and plant cell membranes [84]. PLs are arranged as lipid bilayers with the hydrophilic regions reaching toward the outer surface of the cell membrane and the hydrophobic properties reaching toward the inner membrane compartment. PLs can be glycerophospholipids (GPLs) found in most cell membranes or sphingophospholipids (i.e., sphingomyelin or SPM), commonly found in high quantities in the brain and neural tissues [84]. Cell membranes are also composed of glycolipids and cholesterol and proteins.

GPLs can be extracted from soybeans, egg yolk, milk, or marine organisms such as fish, roe, or krill [84]. GPLs can have different fatty acid compositions. Soybean PL consists of GPLs with a high content of unsaturated FA such as LA (n-6 FA); egg yolks have mainly phosphatidylcholine (PC) as their source of PL and contain unsaturated FA, mainly oleic acid; milk GPLs have both PC and phosphatidylethanolamine (PE) as their main PL classes in addition to SPM, and the FA content consists of both unsaturated and saturated; marine GPL is mainly composed of PC and binds the unsaturated eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) [84]. Consuming dietary GPLs with a specific FA composition may alter the FA composition of membrane PLs and affect cellular function such as signaling, transport, and activity of membrane enzymes. The possibility for modulating cell function from specific PLs could contribute to health benefits [84].

A number of possible clinical applications of using phospholipids exists. They involve reducing inflammation; improving lipid profile; increasing production of cytoprotective mucosal PGE2 in the GI tract, which may help with ulcerative colitis or the side effects of using NSAIDs; and improving cognitive function, visual function, and memory [84].

Phosphatidylserine (PS), the best studied GPL for brain performance, may be especially protective against age-related cognitive decline. PS has been shown to revitalize memory, learning, concentration, and vocabulary skills and assist with managing stress hormones and depression [84]. PS also stimulates acetylcholine synthesis, which triggers the release of neurotransmitters. Changes in the composition of cell membranes with age include an increased cholesterol–PL ratio, which may reduce the immunological function of lymphocytes. In a study on rats, lymphocyte number and macrophage phagocytic capacity were significantly improved with soy PC supplementation. PLs (purified extract of PPC from soybeans) have shown a beneficial effect with viral hepatitis and alcohol-induced liver damage. PLs have also been demonstrated to reduce total liver lipid, liver TG, and total cholesterol [84].

Chronic alcohol ingestion depletes PL in brain cell membranes and depletes antioxidant systems from the cell membranes which, in turn, promotes lipid peroxidation in the brain and other cells such as enterocytes [84].

8.8.5 Short-Chain Fatty Acids

Short-chain fatty acids (SCFA) are the major metabolic products formed by anaerobic bacterial fermentation of soluble fiber in the gastrointestinal tract and may be the link between microbiota and host tissues [85]. SCFA include acetate (C_2), propionate (C_3), and butyrate (C_4) [85]. Acetate is utilized for lipogenesis in the liver and as a fuel source once it enters the peripheral circulation; propionate is also used in the liver as a substrate for hepatic gluconeogenesis; butyrate is primarily used as a fuel source for the colonocytes [86]. Besides serving as a fuel source for the intestinal epithelial cells, SCFA also modulate electrolyte and water absorption in the GI tract and regulate the inflammatory process in the GI tract [85]. The concentration of SCFA in the GI tract and blood may predispose to or prevent illnesses such as inflammatory bowel disease (IBD), cancer, and diabetes [85]. SCFA modulate different processes such as cell proliferation and differentiation, hormone secretion of leptin and peptide YY, and immune and inflammatory responses and serve as an energy source for colonocytes, the liver, and muscle [85]. SCFA levels have been found to be lower with increasing age in humans, dogs, and mice [86].

Butyrate is the most widely studied SCFA and is predominantly produced by *Faecalibacterium prausnitzii* (*F. prausnitzii*). Butyrate serves as an energy source for colonocytes and exerting an anti-inflammatory effect in the colon [87]. Studies reported benefit when butyrate was administered for IBD-related lesions and symptoms [87]. A study by Zhang et al. in rats found that oral administration of butyrate resulted in increased percentage of butyric acid, fecal concentration of butyric acid, and overall total SCFA [87]. Studies in mice have suggested that the obese microbiota, which has a higher ratio of *Firmicutes* to *Bacteroidetes* compared with lean microbiota, produce a higher amount of SCFA compared with leaner counterparts, potentially contributing to obesity [86].

The reasons for higher SCFA in obese individuals may be due in part to lower colonic absorption of SCFA, reduced colonic transit time, or increased SCFA production due to differences in dietary intake [86]. The ratio of *Firmicutes* to *Bacteroidetes* in humans is not always higher in obese individuals; thus, the higher SCFA theory in obese individuals is not a consistent finding [86]. A study by Rahat-Rozenbloom et al. comparing obese versus lean subjects suggested that

SCFA production was higher in obese individuals, but this was not due to decreased absorption of SCFA or differences in dietary intake. Rather, this may be due to the differences in the microbiome with the obese microbiome being higher in *Firmicutes* than the lean microbiome [86]. Further research will be critical in finding the important relationships.

Increasing the production of SCFA is largely accomplished by eating a whole-foods diet high in plant foods and fiber. Butter is a natural food source of butyrate. Butter from grass-fed cows would provide the additional benefit of the anti-inflammatory effects of the fatty acid CLA. In cases such as IBD, a high-fiber diet may not be tolerated during an exacerbation of the illness, and this is where the oral or enema administration of butyrate might be of benefit. Working with an experienced integrative and functional medicine practitioner in the use of butyrate is recommended.

8.8.6 Increasing Beneficial Fatty Acids

Increasing omega-3 fatty acid intake might include eating grass-fed beef (also high in CLA), wild-caught fish, eggs from free-range chickens with omega-3 fatty acids in their feed, and supplementing with omega-3 fatty acids. Simopoulos et al. recommend lowering omega-6 by changing vegetable oils from corn, sunflower, safflower, cottonseed, and soybean oils to oils that are high in omega-3, such as flax, perilla, chia, rapeseed, and oils that are high in monounsaturated fats such as olive oil, macadamia nut oil, hazelnut oil, and increasing fish intake to two to three times per week while decreasing meat intake [74]. Processed foods are notoriously high in omega-6; therefore, consuming a whole-food, unprocessed diet is also an important factor in balancing the ratio of omega-6–omega-3 fatty acids. Increasing GLA involves supplementing with a good source of GLA, such as evening primrose oil, black currant seed oil, or borage oil. Increasing CLA can be done through supplemental sources that include a variety of isomers or eating grass-fed beef and whole-fat dairy products from grass-fed beef, such as butter, yogurt, cheese, or milk, and enhancing the microbiome through diet to support the endogenous biohydration of LA. Increasing phospholipids such as choline can occur through eating sunflower seeds, egg yolks, fish, and milk. Sunflower or soy lecithin are both sources of phospholipids (sunflower lecithin is typically recommended over soy lecithin) and dietary supplementation of phosphatidylserine and phosphatidylcholine.

8.8.7 Assessing Erythrocyte Fatty Acid Profiles

Because a "one-size-fits-all" approach to fatty acid supplementation is not optimal for balancing fatty acid nutritional status, testing erythrocyte fatty acid profiles is a helpful tool as a part of nutritional assessment. Assessing fatty acid profiles in packed erythrocytes is the most common procedure and is representative of longer-term dietary intake rather than recent dietary intake as is represented in plasma profiles of fatty acids [81]. Fatty acid analysis can also help pinpoint certain key vitamin and mineral needs. Laboratory profiles of fatty acids include more than 40 analytes that may be evaluated using patterns within families rather than assessing each individual fatty acid [81]. Individual variability of intake, digestion, absorption, and degradation can produce different fatty acid profiles and support the notion of not using a "one-size-fits-all" approach to recommending supplemental fatty acids [81]. The assessments of patterns include general fatty acid deficiency, omega-3 deficiency or excess, omega-6 deficiency or excess, hydrogenated oil toxicity, micronutrient deficiency, metabolic and genetic disorders, and fatty acid ratios and indices [81].

RBC fatty acid profiles can indicate certain micronutrient deficiencies. For example, when biotin is deficient, the ratio of vaccenic acid to palmitoleic acid is significantly lower. Vaccenic acid has large effects on membrane fluidity and inhibition of tumor growth in cell culture [81]. B12 deficiency is associated with abnormal fatty acid synthesis that results in odd-chain fatty acids building up in the lipids of the nervous system. This results in altered myelin integrity and demyelination, leading to impaired nervous system functioning [81]. Moreover, this may in part explain the neuropathy associated with cobalamin deficiency [81].

To further elucidate this metabolic process, the production of fatty acids with odd numbers of carbon atoms is initiated by propionic acid [81]. Propionic acid requires B12 to be converted into succinate; therefore, a deficiency of vitamin B12 results in the accumulation of propionate and a build-up of odd-numbered fatty acids [81]. In animal studies of biotin deficiency, abnormalities from the accumulation of propionate have been shown to occur. These abnormalities result in the buildup of odd-chain fatty acids in the plasma phospholipids, plasma, and liver in experimental animals [81]. Gut bacteria in ruminants also produce high amounts of propionate. Consequently, eating animal and dairy products may result in accumulation of odd-numbered fatty acids [81].

Zinc may be the best-known nutritional deficiency that can show up in a RBC fatty acid analysis. The desaturase enzymes needed for the conversion of fatty acid substrates into products rely on zinc. The delta-6-desaturase enzyme that converts LA to DGLA will be under-functioning in zinc deficiency; thus, an elevated ration of LA–DGLA is a sensitive marker for zinc deficiency [81]. In cases where LA-rich foods are restricted and extra flaxseed oil is used, the ALA–zinc ratio may also be elevated as that pathway requires zinc [81].

Essential fatty acid deficiency will show up as an elevation in mead acid [81]. The production of mead acid rises as EFA intake falls. Mead acid is an omega-9 PUFA produced by repeated desaturation of nonessential fatty acids. Mead acid cannot participate in eicosanoid formation but mimics membrane fluidity action of PUFAs derived from EFA.

When supplemental fatty acids are used, they must be kept from air and light to keep oxidation low. In addition,

these supplements often contain vitamin E to help prevent oxidative damage to the fatty acids [81]. Erythrocyte fatty acid follow-up testing is recommended to be done after 90 days of starting interventions [81].

8.8.8 Hydrogenated Oils

Hydrogenated oils are harmful fats also known as trans-fatty acids. Hopefully, trans-fatty acids will be less of a concern in the United States due to the phasing out of these fats in the food manufacturing industry. Trans-fatty acids are harmful because, although listed as unsaturated fats, they behave like saturated fats and lead to higher cholesterol levels, and they mimic unsaturated fats by binding to desaturase enzymes and interfering with the normal production of necessary substances [81]. Trans-fatty acids have been shown to contribute to the risk of heart disease and cancer [81]. Trans-fatty acids are found in margarine, hydrogenated peanut butter, baked goods, desserts, snack foods, and crackers [81]. The main trans-fatty acid type found in hydrogenated foods is C-18 trans-fatty acids including elaidic acid, trans-vaccenic, and trans-petroselinic, followed by palmitelaidic acid.

Milk products and beef can contain some naturally occurring trans-fatty acids (elaidic acid) formed from the bacteria in the gastrointestinal tract of ruminant animals [81]. Naturally occurring trans-fatty acids are not a health concern [81].

8.8.9 Overall Diet and Macronutrient Distribution

Diet is the core treatment for many diseases, including obesity, hypertension, hyperglycemia, and dyslipidemia. Many interventions are beneficial, including replacing harmful fats with health-promoting fats; increasing fiber; increasing phytonutrient content such as flavonoids, polyphenols, and antioxidants from plant-based foods; reducing salt; and restricting calories [88]. The Mediterranean diet is one of the most studied diets and recommends high consumption of extra virgin olive oil, fruits, vegetables, nuts, seeds, legumes, cereals, moderate fish, poultry, dairy, and red wine and lower consumption of eggs, red meat, processed meat, and processed foods. The Mediterranean diet improves blood pressure, lipid profiles, insulin sensitivity, CRP, oxidative stress, atherosclerotic disease, and cognitive function [88]. The Mediterranean, pescetarian, vegetarian, or vegan diets also offer environmental benefits with decreased greenhouse gas emissions [88]. People who eat an organic, Mediterranean diet may contribute to a reduction in global environmental impact [88]. In terms of lowering of HbA1C, a systematic review found that a low carbohydrate Mediterranean diet and low-fat vegan diet were possibly the most effective [89].

To reemphasize, a one-size-fits-all diet or macronutrient recommendation is not plausible. The percentage of calories from carbohydrate, fat, and protein needs to be determined on an individual basis. Specific conditions such as chronic kidney disease will benefit from a controlled protein intake, and epilepsy can benefit from a very low-carbohydrate, high-fat ketogenic diet. For years, the field of nutrition has been bombarded with claims of various adjustments in macronutrient ratios having benefit. Nutritionists need to take into account individual disease states and give the patient the most sustainable, realistic plan to improve health.

While the ketogenic diet (low-carbohydrate, high-fat) is showing promise for various conditions including epilepsy, cancer, weight loss, type 2 diabetes, metabolic syndrome, dementia, and neurological diseases [90], the ketogenic diet can be difficult for the average person to sustain. The guidance of a ketogenic-trained nutritionist can assist in compliance. This dietary regimen can be a critical intervention to produce a successful outcome. It is important that a ketogenic or modified ketogenic diet regimen be developed for the individual and their medical condition. In this author's opinion, intermittent fasting (IF) and time-restricted feeding (TRF) may prove to have as important cardiometabolic and neurological benefits as the ketogenic diet and may be appropriate for those who cannot sustain a ketogenic diet.

Time-restricted feeding (TRF) may be a feasible alternative to calorie restriction, ketogenic diet, and intermittent fasting when compliance with more restrictive eating regimes is not likely or not recommended. TRF is an eating pattern based around circadian rhythms that occurs within a limited time span (usually 8–12 hours), with a span of 4 hours in between meals with no attention paid to calorie intake [91]. In one study, eight overweight participants consumed their entire caloric intake within a 10–11-hour window. These participants consumed 20% less calories (due to eliminating alcohol and late-night snacks) and lost 4% body weight in 16 weeks that they sustained for 1 year. The participants reported improved sleep and elevated alertness during the day [91]. TRF can impart other benefits as well. Prolonged overnight fasting (>13 hours) correlated with reduced risk of breast cancer [91]. TRF is still being investigated, and more studies are needed to validate its effectiveness.

Correcting nutritional imbalances by designing individualized food and dietary supplementation recommendations are the cornerstone of functional nutrition.

8.9 Summary

Nutrient intake is a contributing factor to living with or without disease. Correcting nutritional imbalances by designing individualized food and dietary supplementation recommendations are the cornerstone of integrative and functional nutrition. When using supplements, always keep balance in mind. Retest lab parameters to ensure clients are staying in balance. Adjust dietary macronutrient ratios according to individual needs instead of using a one-size-fits-all approach (See ► Box 8.1).

Box 8.1 Recommendations for Assessment-Based Interventions

- Using the ingestion–digestion–utilization (IDU) worksheet can help to pinpoint which additional tests need to be ordered to better assess nutritional balance.
- Dietary intake may be assessed to see what nutrients are low in the overall dietary intake.
- A micronutrient test can look at individual nutrients in the red blood cell or plasma and RBC fatty acid status.
- Plasma or urinary amino acid testing can be used to assess amino acid status as it relates to behavioral and neurotransmitter function and overall adequacy of nutritional intake.
- Waist circumference and BMI can be used to determine what macronutrient distribution, and calorie level might be best suited for an individual.
- Nutrition physical exam and conventional lab tests such as a CBC can give an indication of protein status, electrolytes, iron, and vitamin B12 status:
  - HBA1C and fasting insulin can be a guide toward adjusting carbohydrate in the diet.
  - Lipid profiles and RBC fatty acids can be combined together to determine the type and quantity of fat and carbohydrate that needs to be included in the diet.
- Comprehensive stool and digestive analysis can give an indication as to how the person is digesting and absorbing their food and the need for digestive or pancreatic enzymes:
  - This test can also identify any pathogens that might be contributing to malabsorption.
  - The need for hydrochloric can also be determined by assessing symptoms such as gas and bloating right after meals, nail strength, easy hair pluckability, serum protein and albumin as well as looking for any protein fragments in the stool analysis.
  - Fat malabsorption may be assessed by looking at fat in the stool and serum levels of cholesterol and triglycerides that are often low normal in conditions of fat malabsorption.
- Antioxidant status can be assessed by integrative nutritional testing that looks at lipid peroxidation and glutathione status and levels of CoQ10, vitamin E, selenium, and zinc.
  - Simple questioning that can assess the quantity of fruits and vegetables, nuts, and legume servings can also give an indication of the level of antioxidants and phytonutrients the person is consuming.
- Vitamins A and D may be assessed by testing serum retinol levels and vitamin D3 (25, OH).
- Ferritin levels may give a more accurate assessment of iron status than hemoglobin or hematocrit.
- Dietary and laboratory assessment and a nutrition physical exam are key tools for identifying clinical and subclinical nutrient deficiencies that could be derailing an individual's ability to achieve an optimal and more functional state of health:
  - Optimizing nutritional status can be pivotal for helping people turn the corner with their health challenges.

9.1 Introduction

An integrative assessment and diagnosis of each individual is fundamental to identifying root causes for an appropriate intervention. Because of the complexity of human metabolism and the diverse influences, the NIBLETS assessment was developed as a way to assess factors that are affecting nutrient metabolism. The NIBLETS model is named for its seven components:

- *N*utrient deficiencies/insufficiencies
- *I*nflammation/immunity
- *B*iochemical individuality (genetic/epigenetic influences on chronic disease)
- *L*ifestyle factors
- *E*nergy
- *T*oxic load
- *S*tress and sleep

Historically, nutrition assessment focused on evidence-based research, nutrient requirements of populations, and dietary intake. IFMNT expands this population-focused nutrition assessment by assessing the individual and their unique nutrition status at the time of the assessment. The individual's nutrition status becomes the foundation on which interventions are based, within the safety of evidence-based medicine and clinical expertise. Many of the tools that IFMNT practitioners have found useful in performing a NIBLETS assessment are included in this textbook, with further description of each of the NIBLETS categories.

One of the most beneficial tools used by the IFMNT practitioner when assessing nutrient status is laboratory testing of various components of the body: blood, saliva, urine, breath, stool, and others. Integrative laboratory testing can reveal the deeper, unseen, and otherwise unidentified issues that linger underneath the surface. However, a practitioner can begin a differential nutrition assessment through the NIBLETS lens prior to receiving any test results, immediately after hearing a patient's story. Whereas the patient's story will cover their medical history, this part of the assessment considers the current modifiable factors and clinical imbalances that influence an individual's health. To treat a person rather than a condition requires a thorough assessment of external factors negatively impacting that person's health. Regardless of the advances in pharmaceutical and nutraceutical support the medical community is able to make, patients will find themselves in a similar position once again if interventions are not made to change the patterns that helped cause the problem in the first place. In order to inform these changes, a thorough assessment and diagnosis must first be made. In this section we will outline the seven components of the NIBLETS model and discuss the benefit of using the integrative NIBLETS assessment for determining an individual's nutrition and metabolic status.

9.2 N: Nutrient Deficiencies/Insufficiencies

Medical history/current condition/diagnosis When assessing an individual patient, the patient's medical history and current condition or diagnosis can guide initial considerations, based on evidenced nutrient foundations for that condition or diagnosis. For example, for a patient presenting with a diagnosis of heart disease, nutritional-metabolic concerns would focus on lipid metabolism, vitamin D, and inflammation. If a patient presented with type 2 diabetes mellitus, one would consider carbohydrate metabolism, vitamin D, and nutrients required for glucose/insulin metabolism. Each health condition will have nutrient-related considerations that have shown particularly strong associations or causal relationships. The assessment investigation can begin with these considerations.

Dietary intake The foundation of any person's nutritional sufficiency is his/her dietary intake to meet individual biochemical nutrient needs, which are influenced by genetics and environmental stressors. The Standard American Diet, consisting of mostly nutrient-poor processed and fast foods, has left the majority of the public overfed and undernourished. While over 70% of US adults are considered clinically overweight or obese, theoretically consuming more calories than needed, they are still not consuming adequate amounts of essential nutrients. Three-quarters of Americans consume less than the recommended intake of vegetables and fruits, and that is when fried potatoes and refined juices are included in these counts [1]. The majority of Americans are not even reaching the estimated average requirement or adequate intake of potassium, fiber, choline, magnesium, calcium, and vitamins A, D, E, and C [1]. Meanwhile, these standards for nutrient consumption are currently based on average needs for our population to remain in a disease-free state. For many individuals, nutrient needs may actually be much higher for optimal function, driving the chasm between need and intake even wider.

Reliance on convenience foods and the dissipation of the family dinner table is certainly a lifestyle factor affecting our nutrient status. Within the span of less than 30 years starting in the late 1970s, Americans' consumption of food prepared outside the home, as a percentage of total calories consumed, nearly doubled [2]. This has a direct correlation with decline in diet quality [3]. However, even within the home, the standard American way of eating is heavy in refined grains and added sugars and increasingly lacking in whole, nutrient-dense foods. The current hurried lifestyle pattern in the USA leaves very little time for the food preparation involved in cooking tasty meals containing nutrient-dense foods such as quality proteins and vegetables. In 2014, the average American spent roughly half an hour each day on preparing food and cleaning up. However, between those who used any restaurant foods on a regular basis and those who did not, there was a 30-minute discrepancy in daily time spent on food preparation [4]. Considering our currently overworked,

under-rested, hurried lifestyles, it is no wonder why these convenience foods are highly sought after. For this reason, intervening to improve diet quality will undoubtedly require directives on addressing these time and budget constraints (see ► Chap. 2).

In addition to the typical dietary patterns of the Standard American Dieter, those who follow restrictive diets such as vegetarianism and veganism are at risk for further nutrient deficiencies. While many factors may lead a person to this dietary pattern including moral, religious, or even health-based motivations, it is still worth noting the increased risk. In addition to the aforementioned nutritional deficiencies for those with a Western-style diet, those who avoid animal products are at further risk of inadequate intakes of protein, omega-3 fatty acids, vitamin B12, iron, zinc, vitamin K2, and iodine. While a nutritionally adequate diet can still be achieved, special attention should be given to those adopting this dietary pattern to address the higher risk.

Laboratory testing Lab testing is a valuable component of a nutrition assessment, as it can provide insight and information that is hard to identify through symptoms alone (i.e., infections, nutrient deficiencies, hormonal imbalances, etc.). While there are many different forms of testing – such as micronutrients, stool, urine, and saliva – not all are equal, nor do they test the same things. For example, a urine organic acid test is valuable to assess a patient's methylation function, while a comprehensive stool analysis is valuable to assess a patient's gut health and microbiome status. Both tests are valuable, but both might not be necessary for every patient. During a nutrition assessment, the practitioner can gather information and use clinical judgment to determine which laboratory testing would provide additional data necessary for that patient.

There is no "perfect" method of testing for nutrients. Many forms of testing are currently available, including serum, red blood cell (RBC), lymphocyte, stool, urine, and hair. Labs are a tool to be used in conjunction with the rest of the nutrition assessment. If laboratory testing is ordered, even if it isn't direct nutrient testing, the results can provide guidance to the practitioner on what dietary, lifestyle, or supplement changes need to be made.

IFMNT practitioners look beyond population guidelines. Instead, they look at the individual and work with each individual to optimize the body. Identification of an individual's current nutrient status via laboratory testing can provide answers and guidance for a proper intervention for the patient.

9.3 I: Inflammation/Immunity

The inflammatory and immune responses to injury and infection are essential for host defense and survival. However, these responses carry a significant metabolic burden, driving the need for certain nutrients. Furthermore, both micro- and macronutrient deficiencies can cause immune dysfunction, increasing the likelihood of inappropriate inflammation or infection. Therefore, since the relationship between nutrient status and immunity is bidirectional, assessing a patient for both is crucial to determining an appropriate and effective intervention.

Acute immune response requires many different nutrients for both initiation and resolution. Adequate nutrition is needed for both adaptive and innate immune responses. Undernutrition is recognized worldwide as a major contributor to poor survival in developing countries. However, even in populations of adequate food access, hospitals are screening for malnutrition because of its association with increased complications and mortality [5]. In the case of starvation, immune function can be impaired quickly because of the lack of nutritional reserve within immune cells. Undernutrition is known to alter both innate and adaptive immune responses, including T-cell proliferation and function [6]. However, micronutrient status has been one vastly overlooked area, particularly in acute settings, though two-thirds of patients hospitalized in an infectious disease clinic were found to be deficient in at least one nutrient [7]. Vitamin A, vitamin D, vitamin E, zinc, omega-3 fatty acids, and omega-6 fatty acids are among the most-studied nutrients active in the immune response, though many other nutrients play integral parts in the optimal function of the immune system. Therefore, a complete nutritional assessment would include looking for macro- and micronutrient deficiencies.

However, the relationship between inflammation and nutrition is rather complex and can lead to a cyclical issue. While malnutrition certainly increases susceptibility to illness, inflammation can in turn promote nutrient deficiencies. Many immune or inflammatory processes drive consumption of certain nutrients, such as in the case of conditionally essential amino acids. Other inflammatory conditions, such as in the case of infection, can also indirectly cause nutrient deficiencies by increasing intestinal permeability or anorexia. Therefore, using an integrative assessment can help pinpoint the root cause of the issue so it can most effectively be addressed.

Prolonged inflammation contributes to the progression of many chronic diseases, such as types 1 and 2 diabetes mellitus, cardiovascular disease, Alzheimer's, psoriasis, lupus, and more. Modifiable lifestyle factors including diet, smoking, and exercise have profound impacts on these levels of inflammation. While acute inflammation is necessary for healing, chronic, low levels of inflammation appear to be major players in chronic disease etiology. Immune dysregulation and oxidative stress are closely related to inflammation in the body, with common etiology and positive feedback loops, compounding the detrimental impacts. For many, this inflammation may go undetected for years, leading it to be termed the "silent killer" by scientific and media reports. Regardless of a symptom manifestation, chronic inflamma-

tion poses a damaging impact, increasing risk of chronic disease and mortality. Western lifestyle behaviors such as poor diet, inactivity, and smoking are often underlying root causes of this inflammation.

Diet is a major player in this underlying inflammation. Red meat consumption, for instance, has shown to stimulate the production of the prooxidant trimethylamine-N-oxide (TMAO) 3.7 times more than chicken in rat models [8]. Excess consumption alone can be a stimulant for inflammation. Hyperinsulinemia caused by excess carbohydrates and calories has a pro-inflammatory effect. High-carbohydrate diets have been associated with a greater likelihood of having an elevated hs-CRP in postmenopausal women [9]. Furthermore, excess adiposity, particularly in regard to white and/or visceral adipose tissue, contributes to the circulation of pro-inflammatory adipokines such as leptin and is associated with increased levels of interleukin-6 and tumor necrosis factor alpha [10].

Immune responses to both acute and chronic inflammatory responses involve complex molecular signaling. One major pathway at play involves the eicosanoids, which are derived from polyunsaturated fatty acids. The relative production of anti-inflammatory prostaglandin eicosanoid (PGE)-1 or PGE-3 versus pro-inflammatory PGE-2 directly modulates the inflammatory state. Because PGE-3 is derived from omega-6 fatty acids and PGE-2 from omega-3 fatty acids, balancing fatty acid intake is crucial to creating an optimal environment. These two fatty acids and their subsequent metabolites compete for space within the cellular membrane, cleavage from the cell by phospholipase A2, and further metabolism by delta-5 and -6 desaturases. While current dietary guidelines for Americans recommend increasing intake of all polyunsaturated fatty acids, evidence suggests that increasing omega-6s without increasing omega-3s increases the risk of CVD events, further confirming how critical the appropriate ratio is for balancing inflammation. In fact, having a higher omega-6/omega-3 ratio in the diet has shown association with a higher level of CRP [11]. Though determining an optimal ratio for PUFAs is difficult, experts suggest a range between 1:1 and 4:1 in omega-6 to omega-3 FAs [12]. Because of the omega-6 fatty acids in cheap oils such as corn, soybean, and cottonseed used in processed and restaurant foods, the Western diet has an estimated 20:1 ratio, leaving its consumers with cells primed for propagating inflammation.

Conversely, diet can be used therapeutically to reduce chronic inflammation. Those who followed a Mediterranean or Paleolithic pattern of dieting have been found to have lower levels of hs-CRP [13]. Similarly, those who had higher scores on the Alternative Healthy Eating Index or were able to improve their scores over a 6-year period had lower levels of IL-6 [14]. This is likely related to the high antioxidant and fiber intake found within these dietary patterns. Antioxidants work to quench free radicals, halting the propagation of lipid peroxidation. Having a higher intake of foods rich in antioxidants relative to those devoid of antioxidants alone is associated with a lower C-reactive protein level, as well as a decrease in systolic and diastolic blood pressure [15]. As noted previously, omega-3 fatty acids have a large anti-inflammatory effect because of their eicosanoid metabolites and downstream resolvins and protectins, which have an inflammation-resolving impact. Furthermore, negative attributes of the Western lifestyle may act synergistically to either counteract or compound the inflammation. Mice exposed to cigarette smoke have shown increased oxidation levels when fed a high-refined-carbohydrate diet [16] and protection from the oxidative damage when given omega-3 fatty acids [17].

Beyond the direct influence on inflammation, lifestyle factors also influence our immune system through various mechanisms. Generally speaking, obesity preferences Th1 and Th17 dominance over Th2, promoting inflammation. Visceral adiposity, in particular, appears to contribute to this immune and inflammatory dysregulation because of the macrophage infiltration of the adipocytes. These macrophages promote the Th1 dominance through the release of IL-6 and IL-1 and TNF-alpha [18]. Furthermore, the health of the gastrointestinal system is a major factor in determining the health of our immune system. It is known as our first line of defense against pathogens. Unfortunately, the Western style of living with stress, poor diet, and toxin exposure has led to the rise in intestinal permeability, impacting the integrity of the gut lining. This leads to a greater susceptibility of pathogens to escape defenses of the gut and enter circulation. Diet, by promotion of a healthy microbiome, affects adaptive immunity. A healthy diet rich in fiber leads to a rise in beneficial bacteria that produce metabolites acting as ligands on aryl hydrocarbon receptors (AHR) found in the mucosa of the intestinal lining. The activation of AHR promotes the differentiation of T cells into T-regs. Nutrients such as vitamins A and D also have direct impact on the adaptive immune system. Vitamin A is needed for stability of Th1 response, in such a way that a deficiency has been shown to stimulate Th1 in allergic diseases. Synergistically, vitamin D when binding to a vitamin D receptor heterodimerizes with vitamin A receptor RXR, promoting T-cell differentiation to T-regs and inhibiting IgE synthesis [18].

Considering the complexities of the relationship between inflammation and nutrition, a deeper, integrative assessment of an individual is necessary for determining nutrient status. First of all, the discovery of chronic inflammation in most cases should indicate a greater nutrient need, due to its impact on malabsorption in the gut. However, determining adequate status can also prove difficult. For instance, several nutrient laboratory values are known to be altered in inflammatory conditions, mostly because of changes in acute-phase reactants. Vitamin A is a one example of this. Serum levels of vitamin A do not accurately reflect liver stores during an inflammatory response. Therefore, assessment of vitamins without knowledge of inflammatory status could lead to inappropriate supplementation. Conversely, ferritin, the storage form of iron, is elevated during times of inflammation, potentially masking a deficiency. For this reason, an integrative assessment demands looking at the inflammatory and immune status in conjunction with nutrient status to determine the patient need (Table 9.1).

Table 9.1 Assessment for inflammatory/immune status

Assessment category	Markers of inflammation/immune status
Biomarkers	Hs-CRP, fibrinogen, myeloperoxidase, WBC,
Physical exam	Large waist circumference, excess adiposity, edema
Symptoms	Chronic pain/aches, bloating, swelling, weight gain

9.4 B: Biochemical Individuality and Genetic/Epigenetic Influences on Chronic Disease

IFMNT skills start with the medical condition or symptoms, and then an assessment is completed using the NIBLETS differential. The evidence gathered is the baseline to consider corrective interventions where nutritional injuries/altered nutrition status have been identified. With technological and scientific discoveries of the past few decades, the tools of assessment have expanded tremendously. Biochemist Roger Williams was the first to gain recognition for the term "biochemical individuality" after he published his book *Biochemical Individuality* in 1965. He led a movement toward understanding the origin of disease through the concept of biochemical individuality, which he defines as "the anatomical and physiological variations among people and how they relate to their individual responses to the environment." He then related this individuality to differing nutritional needs for optimal wellness. Another breakthrough in healthcare came with the recognition that nutritional status and needs can be influenced by genetics. This is another important component in biochemical individuality and has received a significant amount of attention and research over the past several decades. It is well recognized that genetics affect disease risk and are influenced by environment, lifestyle, and nutritional factors.

Before nutrigenomic data was available, inherited or disease tendencies within a family were gleaned assembling a "family history," which would hint at metabolic tendencies that should be considered for an individual. With the discovery of the Human Genome in 2008, the research on nutrigenomics has grown, and so has the availability of genetic testing and analysis (see ► Chaps. 17 and 18). Genetic testing can be extremely valuable information for individualizing or personalizing assessment, as it gives the provider an understanding of molecular-level interactions between nutrients and the patient's genome. If a patient is not responding to lifestyle and diet changes, genetic data can provide more explanations as to why or provide more information on the next intervention to make. Genetic and epigenetic information is an extremely valuable component of the patient's story.

Though genetics are not modifiable, lifestyle habits can modify gene expression through epigenetics. As with any other body system, practitioners must not solely treat the genes but must also consider the many additional factors that influence gene expression. Environment, food, water, stress, gut health, and toxin load can act on various genes both directly and indirectly and alter gene expression. The degree to which any lifestyle factors influence disease states may depend on an individual's genetic makeup.

Genetic information provides additional answers to the question of "why?" Gene expression can be altered by SNPs, nutrient insufficiency or toxicity, toxin overload, and many other factors. Aberrant genes do not, in and of themselves, cause disease. It is now recognized that human genotypes are transformed into human phenotypes as a consequence of environment and lifestyle factors that determine health or disease patterns. The topic of epigenetics and genomics is covered in this textbook in ► Chaps. 17 and 18.

The combination of certain genetic polymorphisms and epigenetic factors may require nutrient support beyond the recommended daily allowance (RDA) if genetic polymorphisms are present and the nutrition assessment or lab results indicate need for nutrient therapy. In these cases, modifications in diet and supplementation can be made. However, just because an individual has certain genetic SNPs does not necessarily mean any intervention is necessary. As with the other components of IFMNT, genetics is one tool in the toolbox for the health provider to utilize but should be considered with the rest of the information gathered in an assessment.

9.5 L: Lifestyle Factors

One key component of an integrative assessment is taking the time to hear a patient's story. In order to truly assess root causes of any health needs, including nutritional deficiencies, a practitioner must also consider influencing lifestyle factors. Sleep and stress are two major lifestyle factors influencing nutrient balance covered later in this chapter; however, other factors such as relationships, activity, and even substance abuse should also be evaluated for their nutritional impact.

Relationships are a major part of an individual's health and well-being. Often, a community or intimate relationships can have a direct influence on diet choices. On a very practical level, positive relationships can allow for easier implementation of nutritional interventions, particularly in the case of caregiver support. Spouses committed to health changes can promote reciprocal behavior in their partners [19]. While they can provide a great support particularly in a battle against chronic disease, stressed relationships can also prevent adequate nourishment and be a burden to one's health. One study showed that men who became divorced or widowed consumed fewer vegetables [20]. Even beyond diet choices, induced stress, potentially from a relational cause, can alter digestive, lipid, glycemic, and inflammatory responses to meals [21]. Considering these relational influences on a patient's dietary choices and metabolism allows for more practical and effective interventions for improving nutritional status.

Physical activity is an integral part of an individual's nutritional status. Physical activity has a long-established role in body composition and nutrient metabolism. However, physical activity is less considered in the context of its influence on nutrient status. Prolonged exercise, because of its metabolic demand, can lend to greater nutrient needs, particularly in the case of electrolytes. For instance, plasma magnesium is depleted following intensive exercise, yet generally rebounds within hours [22]. Therefore, assessment of magnesium status and supplementation interventions should also consider exercise timing. Evidence shows intensive exercise can promote intestinal permeability and, therefore, could influence nutrient status indirectly as well, potentially warranting gut-healing protocols [23, 24]. Furthermore, both excessive exercise and sedentary lifestyles can induce oxidative stress, potentially driving the need for antioxidant nutrients.

Substance abuse is another lifestyle factor likely to influence nutritional status. Alcoholism gives way to susceptibility to multiple nutrient deficiencies via primary or secondary pathways of malnutrition. While many alcoholics simply have inadequate diets by the preference of alcohol over other food and drinks, alcohol can also interfere with the absorption and metabolism of nutrients. The most widely recognized nutrient deficiency common in alcoholics is thiamine. Alcohol inhibits absorption of thiamine, and severe deficiencies can lead to Wernicke-Korsakoff's syndrome [25]. Though less recognized, many other deficiencies are common in alcoholics. Folate deficiency has been found in 80% of hospitalized alcoholics and may be of particular interest due to its role in the hepatic methylation cycle and the observed influence of folate deficiency on progression of liver disease in animal models [26]. Because of the impact of liver disease on production of bile and vitamin carrier proteins (see ▶ Chap. 16), alcoholics are also at risk for depletion of fat-soluble vitamins; however, current recommendations suggest using caution with replacing any of them without initially testing an individual's blood levels [25]. In regards to vitamin A, fatty liver from alcoholism prevents the conversion of beta-carotene to retinol and promotes the excretion of vitamin A from the liver. Therefore, alcoholism can promote functional deficiencies of vitamin A while maintaining serum levels. Understandably, then, correcting the deficiency proves difficult and is cautioned for fear of toxicity [27]. This highlights the need for monitoring blood levels of the fat-soluble vitamins periodically when intervening to replete. Deficiencies in vitamin C and B12, magnesium, and zinc have also been reported in alcoholics, but their direct relationship with alcohol consumption is less understood [25]. Additionally, cigarette smoking appears to directly impact antioxidant levels independent of dietary intake. The evidence is so compelling in this regard that smokers have higher requirements for vitamin C [28]. Additionally, levels of provitamin A carotenoids may also be compromised in smokers [29]. Identifying these modifiable lifestyle factors should be a first-line approach to addressing the nutritional deficiencies at the root cause.

9.6 E: Energy

When assessing the nutrition status of an individual, the energy systems of the human metabolism must be considered. This starts at the most basic level of energy production, within the mitochondria, and expands to a larger assessment of the entire organism's energy balance, which determines an individual's body composition. Nutrient sufficiency is needed at every level of energy production, greatly influencing metabolic pathways and determining phenotypes.

Starting at the cellular level, an integrative practitioner considers the nutrient cofactors and structural components of the mitochondria and cell membrane, where the molecular production of the energy unit of ATP occurs. The practitioner needs to have working knowledge of the primary biochemical systems involved in energy production, such as the citric acid or Kreb's cycle, gluconeogenesis, management of glucose and insulin, and energy fuel sources found in fats. Emerging evidence supports supplementing key nutrients to improve outcomes in conditions of mitochondrial dysfunction such as Alzheimer's and Parkinson's diseases [30]. In fact, a recent trial suggests using serum folate and red cell hemoglobin content levels as a predictive marker of amyloid plaque burden [31]. One of the most-studied nutrients involved in mitochondrial function is coenzyme Q10 (CoQ10). CoQ10 is required for ATP production via the electron transport chain and also has a powerful antioxidant function [32]. Deficiencies in CoQ10 caused by metabolic disorders or statin medications can result in mitochondrial dysfunction and reactive oxygen species [32]. Assessment and repletion of the status of this antioxidant can reduce inflammatory markers [33] and even reduce the atherogenic lipoprotein (a) [34].

Beyond the molecular level, further assessment of a patient's phenotype indicates how those energy systems contribute to chronic disease when energy metabolism is altered. Increased body fat, particularly within visceral adipose tissue (VAT), and the body shape that ensues give clinical evidence that energy is altered in an inflammatory and unhealthful direction. Though very basic in their assessment, anthropometrics can provide a global scale view of energy balance. These assessments include height, weight, body mass index (BMI), and circumferences including arm, waist, and hip. In addition to general energy balance, these measurements have also been indicative of cardiometabolic risk factors, including insulin resistance, inflammation, and triglyceride level in certain populations [35]. Body composition analysis, obtained through a number of techniques such as skin folds, bioelectrical impedance analysis (BIA), and dual-energy X-ray absorptiometry (DXA), can provide a more complete look at body structure beyond a height-to-weight comparison, including distribution of weight among fat and lean tissues and distribution of water in relation to the cell. Because body weight can be deceiving in regard to health status, a body composition analysis providing breakdown of mass will assess excess adiposity or inadequate muscle mass even in an

otherwise "healthy"-weight individual. In fact, BMI alone has shown inaccuracy in predicting cardiometabolic risk in healthy-weight, overweight, and obese individuals [36]. Depending on the body composition test taken, more data may also be available suggestive of a global nutritional balance.

While the assessments at this level tend to lack specificity, they lay the foundation to help direct and prioritize the subsequent steps of the integrative assessment, even in investigating nutrient sufficiency. For instance, obesity alone warrants a deeper look into key nutrients such as vitamin D, whereas wasting or low muscle mass would trigger an investigation of the slew of nutrients associated with undernutrition. In body composition assessments that evaluate hydration status, such as BIA, an imbalance in intracellular vs. extracellular water could suggest evaluating electrolytes. Additionally, the BIA also includes a phase angle, a marker of cell membrane integrity indicative of status of minerals such as magnesium [37, 38], and has also been shown to be predictive of severity of certain conditions such as psoriasis [39] and chronic obstructive pulmonary disease [40]. By including this deeper assessment of metabolism and considering the underlying nutrients driving their functions, an integrative approach expands on the conventional assessment of energy balance for a more complete analysis.

9.7 T: Toxic Load

Just as many nutrients function as cofactors and substrates for gene function, many toxins act as inhibitors or inducers as they impact function and metabolism detrimentally. Both past and present environmental exposures can have an impact on gene expression [41–43] and disease risk as well as a buildup of endogenous toxins overloading an individual's metabolism.

Environmental/exogenous toxins These toxins affect people in different ways, due to differences in body chemistry and effects from the food they eat, genetics, and lifestyle choices. These toxins include pesticides, air pollutants, heavy metals, excessive medications, and various toxins in our food and water supply, as well as the air we breathe. We've recently become aware that the "toxic" effects of electromagnetic frequencies (EMF) on the metabolic pathways may add to a person's total toxin load. Excessive amounts of toxins can impact gene expression and affect many biochemical pathways. If an individual has ineffective and inefficient detoxification processes for reasons such as genetic SNPs, poor nutrient status, or organ dysfunction or removal, or the toxin load is too high for the body to combat, disease may arise. Laboratory testing can help identify levels of some specific toxins, such as heavy metals, and can aid in intervention development.

Though past environmental exposures cannot be prevented, current xenobiotic/exogenous toxins in an individual's environment can be identified and further exposure eliminated. Many of the toxins can be identified through various available testing modalities that can quantify and reveal the impact of residual tissue toxins from past exposures on a person's health.

Endogenous toxins Optimizing management and detoxification of endogenous toxins such as hormonal metabolites, excess stress toxins, and elimination organ processes is directly related to nutrients, food, and lifestyle.

All sources of toxins contribute to the total toxin load, which can benefit by interventions with food, dietary supplements, and other naturopathic interventions that enhance the body's detoxification pathways (see ▶ Chap. 13). Dietary interventions utilizing genetic information, individual nutrition requirements, and other lifestyle factors can be used to prevent, mitigate, and improve chronic disease affected by toxin exposure.

When it comes to total toxin load for an individual, many factors will contribute. Those factors will include some of the more obvious toxin exposures such as cigarette smoke, alcohol, and various drugs, but it will also include car exhaust, heavy metals, paint fumes, Teflon, aluminum cookware, mold, dry-cleaned clothes, pet dander, pesticides, nail polish, hair dyes, perfumes, fertilizers, plastics, etc.

Exposure to polycyclic aromatic hydrocarbons (PAHs) has been shown to impair the immune system through epigenetic modifications [44]. Toxin exposure affects methylation and enzymatic activity, which then influences compound and nutrient production [45]. During an assessment and/or with laboratory testing, the practitioner can get information on the patient's total toxin load and begin to recognize its implications. If the patient has a high toxin load combined with a poor nutrition quality of life and possibly even genetic polymorphisms, then their system will not be working optimally, increasing their risk for disease.

9.8 S: Stress and Sleep

We use the word "stress" in everyday life, yet the meaning is ambiguous. Stress can be traumatic, or it can be eustress (good stress), simply reflecting the daily grind of life. The role of stress in health is well established, yet all too often overlooked by practitioners. Stress has many different triggers with many different manifestations. Therefore, identifying presence of points of stress can be difficult.

Psychoneuroimmunology is a term used to describe the impact of mental attitudes on the body's resistance to disease, especially with respect to the links among and between the mind, the brain, and the immune system. The central nervous system and the immune system have constant communication [46]. Research on the brain-immune system connection has emerged over the last decade [46–48], giving practitioners more evidence to give appropriate attention to the beliefs and feelings of the patient. Cognitive states such as perceived control of a situation, of one's health, view of self,

and views of the future have been linked with immune responses. During an assessment, the conversation about psychological stressors can be initiated through initial paperwork or the flow of the discussion, but for the provider, it's a component that cannot be overlooked.

While short-term/acute stress can be healthy and important for our health (e.g., exercise), chronic/long-term stress is another factor increasing risk for development of chronic disease. After an acute stress response, the main stress hormone, cortisol, lowers again, and the body can return to a balanced state. However, in times of chronic stress, cortisol remains elevated, which has many negative effects on the body [49]. During times of stress, the adrenal glands are working harder to produce cortisol. In this case, they also need additional nutrient support. Nutrients such as magnesium, potassium, and sodium are in higher demand when the body is under stress.

The brain first perceives a stressor and determines what is threatening. It then determines the behavioral and physiological responses to the stressor. Physiologically, the sympathetic and parasympathetic systems, hypothalamic-pituitary-adrenal (HPA) axis, immune system, metabolic hormones, and molecular processes within all organs adjust to combat the response [50]. That is, these organs activate to achieve stability. These adjustments are manageable in the short term, but when they are overused or imbalanced for too long, the body can become overloaded. This overload or imbalance can affect systemic physiology via neuroendocrine, autonomic, immune, and metabolic mediators. Nutritionally, this overload requires more nutrient support [51]. Studies have shown nutrient therapy such as with B vitamins has a beneficial effect on perceived stress, mild psychiatric symptoms, and aspects of everyday mood to support those under chronic stress [52].

9.9 Sleep

Having a properly functioning circadian rhythm is critical to healthy hormonal balance, metabolism function, memory and mental performance, optimal cellular energy production, and the immune system. In fact, one study showed people with chronic insomnia have a three times greater risk of dying from any cause [53].

The modern world sends mixed messages to the brain about whether it's day or night, and the line between sleep and awake can easily be blurred. When the body receives mixed messages, insomnia and fatigue are inevitable results. In contrast, when the right messages are sent, healthy sleep patterns result.

Sleep is essential to health and even if nutrition is optimal but sleep is poor, one's health status will quickly decline. In our modern world and fast-paced society, there are many expectations to do more, which for some people means trading sleep for productivity. This is common for college students, parents of newborns, and many people with demanding careers. Sleep hygiene affects nutrition intake and status, but nutrition intake and status also affect the ability to establish proper sleep hygiene. For some individuals, it's difficult to know which is the root cause of the problem and which should be addressed first or most aggressively. A 1999 study conducted at the University of Chicago concluded that restricting sleep to just 4 hours per night for 7 days led to increased insulin sensitivity and characteristics of diabetes [54]. Additionally, research shows sleep deprivation increases various inflammatory markers including IL-6 and CRP-hs [55]. Research by Van Cauter shows that individuals who are sleep-deprived have an increased appetite, which aligns with other findings that have identified the relationship between short sleep duration and increased intake of unhealthy food with more sedentary habits [56, 57]. Leptin has been proposed as one possible mechanism linked to the increasing rates of obesity. Various studies have indicated a rise in leptin levels after sleep deprivation [58, 59]. This is promising as we know the cravings for unhealthy food are strong and in an environment dominated by processed food, it's difficult to practice willpower, especially when sleep-deprived or stressed. The current research on the neurological connection between sleep, food consumption, and obesity is promising and will, like many other factors in reaching health, require lifestyle changes. A review by Dashti et al. [60] concluded that short sleep duration is associated with higher total caloric intake, higher total fat intake, protein intake, lower intake of fruits and vegetables, and diets of lower quality. Dashti also concluded that behavior and meal timing may also be impacted by sleep. Even changing the timing of meals and/or altering the ratios of macronutrients in those meal times can be a starting place for some people and start the process of reaching better alignment with their natural circadian rhythm. Evidence points to the fact that eating behaviors deviate from the traditional three meals per day to more frequent energy-dense and highly palatable snacks throughout the day and at night. The mechanisms behind these findings linking sleep and dietary intake are likely multifactorial but are important to consider during a nutrition assessment.

When it comes to sleep and nutrition, some nutrients have been studied more than others. Caffeine, for example, has plenty of literature showing an inverse relationship [61]. Not surprisingly, the function of caffeine is evidenced to disrupt sleep quality and quantity. Conversely, vitamin D has also been shown to promote circadian rhythm at a cellular level [62].

Light exposure is the primary regulator of circadian rhythm. Too much light after sunset affects melatonin production [63]. The blue light spectrum from many artificial light sources such as TVs, cell phones, and computers enters the eye and feeds a signal to the brain that "it's daytime." The combination of poor sunlight during the day and excessive blue light at night has major implications on circadian rhythm. Many other factors also contribute to circadian rhythm, including activity, stress, micronutrient status, and transition activities before bed, but each client will have different levels of readiness on where to start.

Bringing awareness to the importance of sleep is step one and can begin during an assessment when collecting information on their habits.

Gut motility is mediated by specific genes expressed in intestinal epithelial cells and in the enteric neurons, which help control circadian rhythm [64]. Colonic motility is faster in the morning and slower at night [65]. Disruption of the circadian cycle can provoke changes in gut motility. Circadian rhythm shifts that occur with traveling, night shifts, or other sleep disruptions can lead to gut symptoms, including bloating, abdominal pain, diarrhea, or constipation [64] (see ▶ Chap. 35).

9.10 Conclusion

A complete and thorough assessment is the crux of an effective practitioner. In order to intervene at the root cause of any condition, the status of the building blocks must first be thoroughly evaluated. Nutrients are the foundation for the body's metabolic processes that ultimately determine one's health. While a conventional nutritional assessment holds merit, it rarely moves beyond intake and expenditure to truly evaluate nutrient utilization and metabolism. Assessing nutritional status through an integrative look at nutrient sufficiency, immunity, biochemical individuality, lifestyle, energy balance, sleep, and stress provides a more complete picture of what interventions need to be made to meet nutritional demands and truly push a patient toward health.

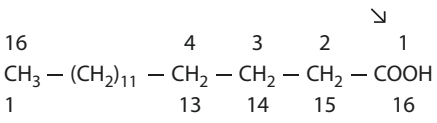
10.1 Introduction

Fatty acids are key components of lipids. They are important dietary sources of energy and have roles in modulating acute and prolonged inflammation [1] and as key components of cell membrane structure [2]. They are called acids because of the organic acid group (COOH) that they contain. They are chains of covalently linked carbon atoms bearing hydrogen atoms. The naturally occurring fatty acids are, for the most part, unbranched and acyclic, but complex structures with branched or cyclic chains also occasionally occur. They have the basic formula $CH_3(CH_2)n{\cdot}COOH$ where n can be any number from 2 to 24. The bulk of the fatty acids in the human body have 16, 18, or 20 carbon atoms, but there are some with longer chains that occur principally in the lipids of the nervous system. One method of fatty acid classification is according to their chain length. Those containing 2–4 carbon atoms are called short-chain fatty acids, while those with 6–10 and 12–24 carbon atoms are called medium-chain and long-chain fatty acids, respectively. In most cases, naturally occurring fatty acids contain an even number of carbon atoms. Fatty acids are also classified as saturated with no double bonds, monounsaturated with one double bond, and polyunsaturated fatty acids (PUFA) with two or more double bonds. Depending on the number of double bonds from 2, 3, 4, 5, and 6, they are called dienoic, trienoic, tetraenoic, pentanoic, and hexaenoic, respectively. The carbon atoms of fatty acids may be numbered either with the carboxyl carbon as number 1 (Δ numbering system) or from the terminal methyl (CH_3) group carbon as number 1 (W or n numbering system).

Δ numbering system (carboxyl side)



The double bond locations are designated by the number of carbon atoms from the carboxyl side or from the methyl side.

Fatty acids are abbreviated in the Δ system by listing the total carbon number and the position of the double bonds. Palmitic acid (which contains no double bond) is abbreviated as C_{16}:0 or C_{16}:Δ_0, and palmitoleic acid which contains one double bond is C_{16}:1 or C_{16}:1 Δ_9. The number after the Δ in this classification system signifies the position of double bond relative to the carboxyl end. In palmitoleic acid, the double bond is in the ninth carbon atom from the carboxyl group. It is between carbon atoms 9 and 10 from the carboxyl carbon as number one. In the W numbering system, palmitoleic acid is abbreviated as C_{16}:1, W_7. This signifies that the fatty acid has 16 carbons and one double bond which is located 7 carbon atoms away from the W carbon counting the W carbon as number 1. In other words, the double bond is between carbon 7 and 8 counting from the W end as shown here:

$$CH_3-CH_2-CH_2-CH_2-CH_2-CH=CH-(CH_2)_7\,COOH$$

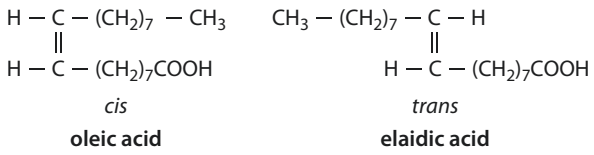
Palmitoleic acid

Table 10.1 lists unsaturated fatty acids of importance in human nutrition using the W numbering system.

Other relevant information is the stereochemical configuration of each double bond. Fatty acids that contain double bonds can exist in two geometric isomeric forms. These forms are known as *cis* and *trans* isomerism. When a double bond occurs along the length of a carbon chain, the pair of the hydrogen atoms on the participating carbon atom may lie on the same side of the double bond; in this case, they are described as *cis* or they may be on opposite sides of the double bond, in which case they are described as *trans*. Double bonds in naturally occurring fatty acids are of the *cis* configuration. Thus, oleic acid is the *cis* form and elaidic acid is its *trans* form [3]:

Table 10.1 Unsaturated fatty acids of importance in human nutrition

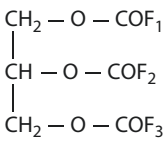
Common name	Systematic name	Structural formula
Palmitoleic	Hexadecenoic (W_7)	$CH_3(CH_2)_5CH=CH(CH_2)_7COOH$
Oleic	Octadecenoic (W_8)	$CH_3(CH_2)_7CH=CH(CH_2)_7COOH$
Linoleic	Octadecadienoic ($W_{6,9}$)	$CH_3(CH_2)_4CH=CHCH_2CH=CH(CH_2)_7COOH$
Linolenic	Octadecatrienoic ($W_{3'6,9}$)	$CH_3CH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_7COOH$
γ-Linolenic	Octadecatrienoic ($W_{6,9,12}$)	$CH_3(CH_2)_4CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_4COOH$
Dihomo-γ-linolenic	Eicosatrienoic ($W_{3,6,9}$)	$CH_3CH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_9COOH$
Arachidonic	Eicosatetraenoic ($W_{6,9,12,15}$)	$CH_3(CH_2)_4CH=CHCH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_3COOH$
	Eicosapentaenoic ($W_{3,6,9,12,15}$)	$CH_3CH_2(CH=CHCH_2)_5CH_2CH_2COOH$
	Docosahexaenoic ($W_{3,6,9,12,15,18}$)	$CH_3(CH_2CH=CH)_6CH_2CH_2COOH$
Vaccenic	Octadecenoic (W_7)	$CH_3(CH_2)_5CH=CH(CH_2)_9COOH$
Nervonic	Tetracosenoic (W_9)	$CH_3(CH_2)_7CH=CH(CH_2)_{13}COOH$



When unsaturated and PUFA are hydrogenated to make margarine and shortening, anywhere from 5% to 70% of the double bonds occur in *trans* form. The *trans*-fatty acids [4] account for 5–8% of the fat in the American diet.

When double bonds of the unsaturated fatty acids are conjugated, that is, the double bonds occur without an intervening carbon atom not part of a double bond, they are called conjugated fatty acids. Conjugated linoleic acid (CLA) occurs naturally in meat and milk food products derived from ruminant sources (e.g., beef, lamb, dairy) because of the process of bacterial isomerization of linoleic acid (present in food stuff for these animals) in the rumen. CLA is higher in grass-fed ruminant sources compared with grain-fed [5].

Fatty acids occur primarily as esters of glycerol when they are being used for energy storage and utilization. Esters of one, two, or three fatty acid residues are called monoglycerides, diglycerides, and triglycerides, respectively. Mono- and diglycerides occur only in minor amounts and largely as metabolic intermediates in the biosynthesis and degradation of glycerol-containing lipids. The bulk of the fatty acids in the human body exist as triglycerides in which all three hydroxyl groups on the glycerol are esterified with a fatty acid. Most triglyceride molecules contain two or more different fatty acid moieties (i.e., the fatty acids within triglycerides are not often repeated) and have the general composition as follows:



where F1COOH, F2COOH, and F3COOH are fatty acid chains that may or may not all be the same.

Triglycerides account for about 90% of the fat in our food and more than 90% of the fat in the body.

There are five categories of fatty acids based on the degree of saturation and types of double bonds. They are saturated, monounsaturated, polyunsaturated, *trans*, and conjugated fatty acids.

10.2 Saturated Fatty Acids

When discussing saturated fats and their nutritional influences on human metabolism, it is important to differentiate between the three main saturated fat categories: short chain, medium chain, and long chain.

10.2.1 Short-Chain Saturated Fatty Acids (SCFA): C_1–C_6 [6, 7]

Understanding the role of SCFAs is important for nutritional modulation of the gut ecology. The short-chain fatty acid substrates result from fermentation between resistant starches and soluble fibers, and beneficial species and amounts of microflora present in the colon. The SCFAs are produced, primarily acetate, propionate, and butyrate, as end products. The SCFAs produced are the primary energy sources for colonocytes and are particularly important for colon health. These SCFAs have anticarcinogenic properties, inhibit the growth and proliferation of tumor cell lines in vitro, induce differentiation of tumor cells, and possess anti-inflammatory properties [8]. Maintaining a life-long colon of healthy cells depend on continual production of SCFAs [8, 9] (Fig. 10.1).

- *Acetic acid (C_2)* does not occur in natural fats and oils, but vinegar contains approximately 5% of acetic acid.
- *Propionic Acid* (C_3)
- *Butyric acid* (C_4) is also uncommon in natural food fats except for milk, butterfat, and breastmilk. A primary endogenous source of butyric acid for its important role as a primary fuel for colonocyte repair is from the healthy colonic microbiome when dietary fiber is fermented in the colon [11].

10.2.2 Medium Chain Triglycerides (MCT): C6–C12 with an Aliphatic Tail [12]

Straight-chain MCFAs are as follows:

- *Caproic acid C_6*
- *Caprylic acid C_8* (n-octanoic acid or fatty acid C8, goat milk, coconut oil, palm oil)
- *Capric acid C_{10}*
- *Lauric acid* C_{12}

MCTs do not require bile salts for digestion. The MCTs are absorbed directly into the portal vein and then transported rapidly to cells and the liver for β-oxidation. Thus, thermogenesis is increased. Because of the ability to be absorbed without requiring emulsification from bile, MCT oils are commonly used in enteral feedings, liver disease diets, weight loss, and others. Patients who have malnutrition, malabsorption, or particular fatty-acid metabolism disorders benefit from inclusion of MCTs in their diet as they do not require energy for absorption, use, or storage. More recently, the MCT oils are universally used in ketogenic diets of all types as they evidence beneficial contributions to brain/nerve metabolism [12]. Substantial amounts of saturated fatty acids are found in certain vegetable products such as coconut and palm oil.

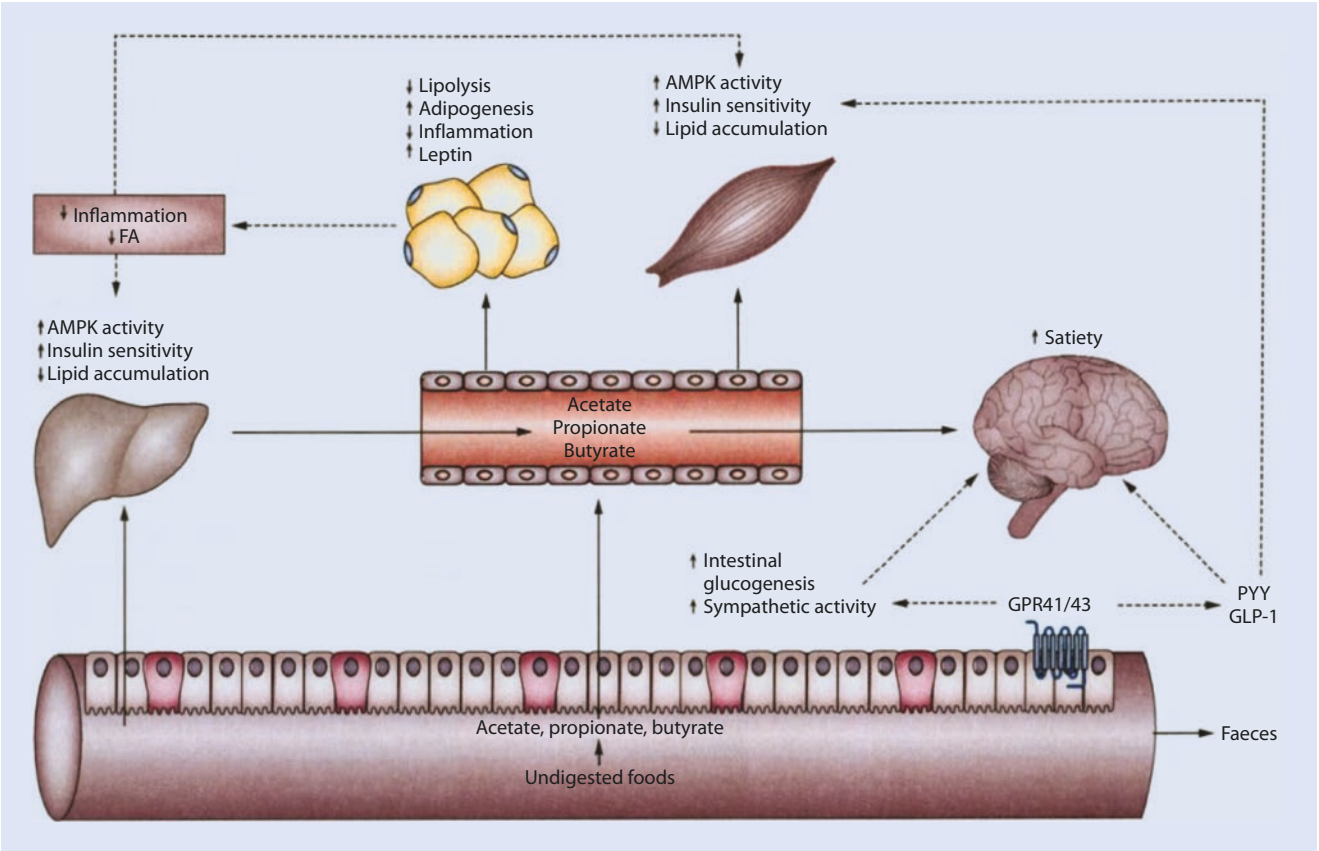


Fig. 10.1 SCFA and interorgan crosstalk [10]. SCFA and interorgan crosstalk fermentation of indigestible foods in the distal intestine results in the production of SCFA. The ratio of acetate to propionate to butyrate in the ileum, caecum, and colon is ~3:1:1. Butyrate and propionate are generally metabolized in the colon and liver and, therefore, mainly affect local gut and liver function. In the distal gut, SCFA bind to GPR41 and GPR43, which leads to the production of the gut hormones PYY and GLP-1 and affect satiety and glucose homeostasis. Furthermore, propionate and butyrate might induce intestinal gluconeogenesis and sympathetic activity, thereby improving glucose and energy homeostasis. Small amounts of propionate and butyrate and high amounts of acetate reach the circulation and can also directly affect the peripheral adipose tissue, liver, and muscle substrate metabolism and function. In addition, circulating acetate might be taken up by the brain and regulate satiety via a central homeostatic mechanism. Whether metabolic effects are mainly explained by direct effects of SCFA or indirectly via gut-derived signaling molecules remain unclear. Solid lines indicate direct SCFA effects, and dashed lines indicate indirect SCFA effects. *Abbreviations*: AMPK adenosine monophosphate-activated protein kinase, FA fatty acid, GLP-1 glucagon-like peptide-1, GPR G-protein coupled receptor, PYY peptide YY, SCFA short-chain fatty acid. (Reprinted from Canfora et al. [6]. With permission from Springer Nature)

10.2.3 Long-Chain C_{13}–C_{21} and Very-Long-Chain Fatty Acids C_{22} or More

These fatty acids are the most abundant in animal and human fats, accounting for 30–40% of the fatty acids in adipose tissue. Substantial amounts of longer-chain saturated fatty acids are found in meat and certain heat- and oxygen-processed oils that are used in hydrogenated shortenings and margarines (Table 10.2).

The saturated fatty acids are not only a source of body fuel but also are structural components of cell membranes. Various saturated fatty acids are also associated with proteins and are necessary for their normal function [14]. They are synthesized as needed by the body to provide an adequate level required for their physical and structural functions.

Saturated fatty acids vary in the degree of cholesterol influence. For example, stearic acid (C_{18}) has little or no effect

Table 10.2 Examples of long-chain and very-long-chain saturated fatty acids

Common name	Chemical structure	*C:D*
Myristic acid	$CH_3(CH_2)_{12}COOH$	14:0
Palmitic acid	$CH_3(CH_2)_{14}COOH$	16:0
Stearic acid	$CH_3(CH_2)_{16}COOH$	18:0
Arachidic acid	$CH_3(CH_2)_{18}COOH$	20:0
Behenic acid	$CH_3(CH_2)_{20}COOH$	22:0
Lignoceric acid	$CH_3(CH_2)_{22}COOH$	24:0
Cerotic acid	$CH_3(CH_2)_{24}COOH$	26:0

Based on data from Ref. [13]

on serum cholesterol, while lauric (C_{12}) and palmitic (C_{16}) dramatically increase cholesterol concentrations. Because palmitic acid is more abundant than lauric and myristic acids, it may be the primary fatty acid affecting cholesterol concentrations. Saturated fatty acids containing 10 carbons or less have not been shown to have any effect on cholesterol levels.

There is no dietary requirement for saturated fatty acids because they can be synthesized endogenously. The average American diet provides approximately 15% of calories in the form of saturated fat. The saturated fatty acid intake ranges from 21 to 34 g per day in men and 15 to 21 g per day in women.

10.3 Monounsaturated Fatty Acids

The liver is the main organ responsible for the endogenous synthesis of monounsaturated fatty acids (MUFA). Monounsaturation at the Δ_9 position is the rule, and in humans the double bond cannot be introduced between carbon 1 and 6 starting from the W carbon of the fatty acids. Therefore, there are only two saturated fatty acids available for desaturation: Palmitic to palmitoleic acid and stearic to oleic acid. On the one hand, MUFA with double bonds occurring before the Δ_9 position are not synthesized to a significant extent by animals and humans because the required desaturase is absent and trace amounts found in animal tissue lipids probably arise from the diet. Plants, on the other hand, can introduce double bonds between Δ_9 and the terminal methyl group.

Plant sources rich in MUFA include olive oil (about 75%). High oleic acid variety sunflower oil contains as much as 80–85% MUFA. Canola oil has about 58% MUFA. It is also found in red meat, whole milk products, olives, and avocados. Oleic acid accounts for about 90% of dietary MUFA. The MUFA, including oleic and nervonic acid (C_{24}:1, Δ_9), are important in membrane structural lipids, particularly nervous tissue myelin. Other MUFA, such as palmitoleic acid, are present in minor amounts in the diet. MUFA neither elevate nor lower the level of serum cholesterol; thus, a high-fat diet is not necessarily associated with a high level of serum cholesterol in the population. Inhabitants in Mediterranean countries consume large amounts of olive oil but tend to have low levels of serum cholesterol. The average American consumes MUFA which makes up about 50% of total fat and provides 20% of the calories in the diet.

10.4 Polyunsaturated Fatty Acids

Humans are not able to introduce double bonds closer to the methyl group than the W_9 position. Thus, two broad classes of biologically active polyunsaturated fatty acids (PUFA) – the W_6 linoleic acid (LA) C_{18}:2, W_6, and the W_3 linolenic acid also called α-linolenic acid (ALA) C_{18}:3, W_3 – cannot be synthesized by humans. These are required for normal growth and function of all tissues. These fatty acids must be supplied by a dietary source [15, 16] and are called essential fatty acids (EFA).

10.4.1 Biosynthesis

The liver is the site of most of the PUFA metabolism that transforms dietary 18-carbon EFA into long-chain PUFA with 20 or 22 carbons. The mammalian tissues contain four series of PUFA. The precursors of the two of these groups are the MUFA palmitoleic and oleic acids, which can be synthesized from saturated fatty acids. The precursors for the other two are necessarily derived from dietary source: LA and ALA. A complex series of desaturation and elongation reactions acting in concert transform the precursors to their higher polyunsaturated derivatives. These four precursors are alternatively desaturated (two hydrogens are removed to create a double bond) and chain elongated (addition of two carbons). The desaturations are catalyzed by Δ6, Δ5, and Δ4 desaturases, and the two carbon additions are catalyzed by elongases to form the principal PUFA found in tissues (Fig. 10.2).

The same enzymes catalyze the equivalent steps in the W_7, W_9, W_6, and W_3 fatty acid pathways, and there is competition among substrates for these enzymes. The critical enzyme Δ6 desaturase displays highest affinity for the most highly unsaturated C_{18} substrate. The order of preference is ALA>LA > oleic acid>palmitoleic acid (provided the substrate concentrations are equal). In the presence of either of the two EFA, little desaturation of oleate occurs. ALA effectively inhibits the desaturation of LA (at equal concentrations). In the absence of the members of the W_6 and W_3 families, however, oleate is desaturated and members of the W_9 family, particularly C_{20}:3, W_9, appear in the tissues [17].

In the desaturation process, additional double bonds are inserted between the preexisting double bonds and the carboxyl group, and the chain elongation always proceeds by the addition of two carbon units to the carboxyl terminus of the fatty acid chain. Therefore, the position of the double bond counting from the methyl (W) end of the precursor fatty acid remains unaltered through all transformations. All products of oleic acid possess the W_9 configuration of oleate itself and are recognized as members of the W_9 family. Nervonic acid C_{18}:1, W_9, a component of nerve tissue lipid, is derived by chain elongation of oleate. Vaccenic acid C_{18}:1 W_7 that occurs in small amounts in tissue lipids is formed by chain elongation of palmitoleic acid. Similarly, LA and ALA give rise to W_6 and W_3 families of PUFA. No interconversion between these families occurs. In addition to desaturases, there is competition of the substrates for chain elongase enzymes and for the acetyl transferases involved in the formation of phospholipids (which require PUFA). Lower members of the family may also be able to compete with some of the products for enzyme sites and the expression of its family. Long-chain highly unsaturated fatty acids can be shortened by two car-

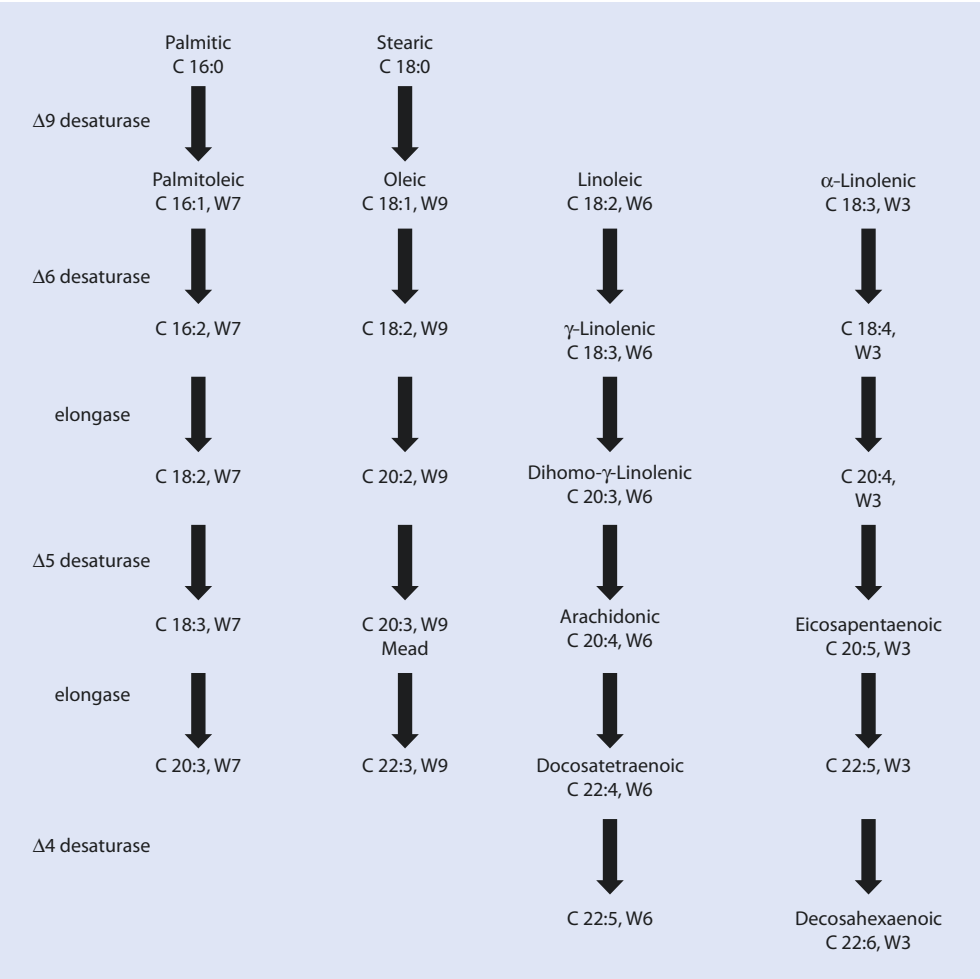

Fig. 10.2 Biosynthesis of polyunsaturated fatty acids. (Courtesy of Vishwanath M. Sardesai, PhD)

bons, a phenomenon called retroconversion. Because of the competition, retroconversion, etc., each family has characteristic end products that accumulate in tissue lipids, while intermediates are usually found in much smaller, often trace amounts. Thus, for oleate and palmitoleate, the major PUFA are the trienes C_{20}:3, W_7, and C_{20}:3, W_9, respectively. For linoleate, the major PUFA are arachidonic acid (AA) with four double bonds (tetraene) and some dihomo-gamma-linolenic acid (DHGL/DGLA). For linolenate, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are the main end products. The 22-carbon hexanoic acid is the most unsaturated fatty acid commonly found in the lipids of higher animals.

Δ6 desaturase is considered one of the rate-limiting enzymes in the metabolic pathway. A typical western diet tends to be much higher in W_6 than in W_3 fatty acids. Although ALA is the preferred substrate for Δ6 desaturase, the excess of dietary LA compared with ALA results in greater formation of AA than EPA. The capacity for conversion of ALA to DHA is higher in women than men. Studies of ALA metabolism in healthy young men indicated that approximately 8% of ALA is converted to EPA and 0.4% is converted to DHA. In healthy young women, approximately 21% of ALA is converted to EPA and 9% is converted to DHA [18]. This better conversion efficiency in young women compared with men appears to be related to the effects of estrogen.

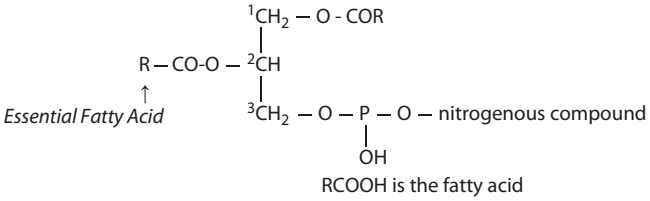
The data from experimental animals suggest that Δ6 desaturase is sensitive to several factors. Those that tend to increase the enzyme activity include a high-protein diet, insulin, and EFA deficiency, whereas fasting, zinc deficiency, aging, glucagon, glucocorticoids, and diabetes are known to decrease its activity. Reduction in the activity of Δ6 desaturase can limit the availability of DHGL and AA, which are required for normal physiologic functions. Although a good deal of AA is acquired from foods of animal origin such as meat and dairy products, little or no DHGL/DGLA is found in a normal diet.

10.4.2 Functions

After ingestion, LA and ALA are distributed between adipose tissue triglycerides, other tissue stores, and tissue structural lipids. A proportion of LA and ALA provides energy, and these are oxidized more rapidly than the saturated and MUFA. In contrast, long-chain PUFA derived from EFA are less rapidly oxidized. These acids when present preformed in

the diet are incorporated into structural lipids about 20 times more efficiently than after synthesis from dietary LA and ALA. PUFA are the major components of structural lipids of membranes of cells, mitochondria, and nuclei, and they play a major and vital role in the properties of most biomembranes. In the phospholipids, the saturated fatty acids preferentially occupy the carbon 1 position and PUFA occupy carbon 2 of the glycerol moiety, although MFUA can also take the carbon 2 position.

Structure of phospholipids:



The physical properties (such as fluidity) of phospholipids are in large part determined by the chain length and the degree of unsaturation of their component fatty acids. The physical properties, in turn, affect the phospholipid's ability to perform the structural function, for example, the maintenance of normal activities of membrane-bound enzymes such as adenylyl cyclase and Na/K ATPase. Several cellular functions which include secretion, signal transmission, and susceptibility to microorganism invasion depend on membrane fluidity. The highly unsaturated fatty acids EPA and DHA are particularly concentrated where there is a requirement for rapid activity at the cellular level, such as may be required in transport mechanism in the brain, its synaptic junctions, and the retina, where only the long-chain PUFA derived from EFA are found. Other biological functions of EFA include stimulation of growth, maintenance of skin and hair growth, regulation of cholesterol metabolism, lipotropic activity, maintenance of reproductive performance, and other physiologic and pharmacologic effects. A few specific functions are given below.

10.4.2.1 Skin

One essential function of LA is to maintain the integrity of the epidermal water barrier in the skin. The physical structure of water barrier is ascribed to sheets of stacked bilayers that fill intercellular spaces of the uppermost layer of the epidermis. These lipid bilayers contain large amounts of sphingolipids which contain LA-rich ceramides. In EFA deficiency, LA is replaced by oleic acid which results in severe water loss from the skin.

10.4.2.2 Immunity and Infection

There is significant reduction in immune response in EFA deficiency. The data from animal studies have shown that these PUFA have powerful anti-inflammatory and immunomodulatory activities in a wide array of diseases (e.g., autoimmunity, arthritis, and infection) [19]. PUFA may cause change in the membrane fatty acid composition of lymphoid cells. This may cause a change in membrane fluidity leading to alteration of activity of enzymes, receptor expression, and intercellular signaling, which in turn can influence lymphocyte responsiveness. Patients with acquired immune deficiency syndrome (AIDS) exhibit significant reductions of 20 and 22 carbon fatty acids derived from EFA. EPA and DHA are thought to be anti-inflammatory nutrients with protective effects in inflammatory diseases including asthma and allergies [20].

Infection is a common clinical problem in patients undergoing fat-free hyperalimentation. Certain PUFA are known to be effective in killing those viruses that have a lipid component in the envelope. Recent study has shown that W_3 fatty acids from fish oil can prevent wound infection and can improve early wound healing. Combinations of W_3 fatty acids with arginine are much more effective in preventing infections than either one alone [21]. The combinations can reduce the incidence of adult respiratory distress syndrome and shorten the hospital stay in surgical patients. Other studies have shown that W_3 fatty acids could help the body fight lung infections common to inflammatory diseases such as chronic obstructive pulmonary disease.

10.4.2.3 Gene Expression

Cell culture and animal studies suggest that PUFA can modulate the expression of a number of genes including those involved in fatty acid metabolism and inflammation [22]. These PUFA may regulate gene expression by acting like steroid hormones [23].

10.4.2.4 Cholesterol

PUFA of both the W_6 (LA) and W_3 (ALA) family tend to lower plasma cholesterol levels, including the low-density lipoprotein (LDL) cholesterol fraction, possibly by increasing the activity of LDL receptors. Many epidemiologic and controlled interventional studies have shown the antiatherogenic effect of both ALA and its long-chain fatty acids. W_3 acids have unique triglyceride-lowering properties not shared by W_6 fatty acids. PUFA, although effective in lowering both total and LDL cholesterol, have a tendency to lower high-density lipoprotein (HDL) cholesterol, which is protective against coronary heart disease (CHD).

10.4.2.5 Eicosanoids

DHGL/DGLA, AA, and EPA are the precursors of biologically potent metabolites. These include prostaglandins, thromboxanes, prostacyclins, lipoxins, and other related compounds. They participate in many physiological and pathological processes. Eicosanoids are compounds with diverse physiological and pathological properties. They are derived from 20 carbon PUFA (e.g., DHGL/DGLA, AA, and EPA). The precursor fatty acids are normally not found in the free state to an appreciable extent in the cell, but occur as esterified components of phospholipids, preferentially located in the carbon-2 position of glycerol (of the membrane phospholipid). In humans, the tissue phospholipid content of AA is much higher than that of DHGL/DGLA and

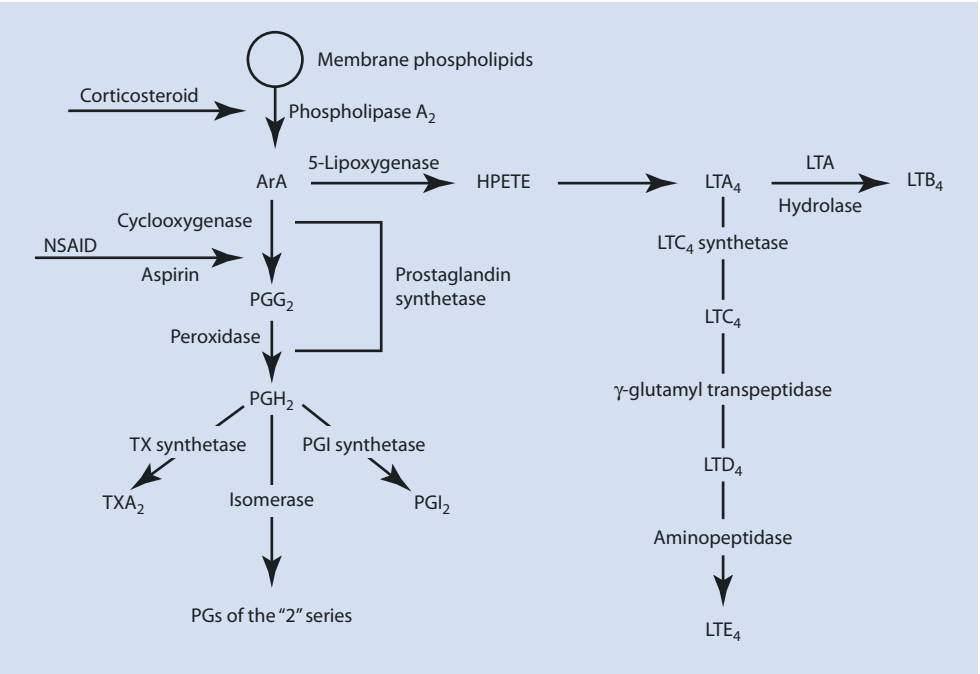


Fig. 10.3 Formation of eicosanoids. The pathway is for arachidonic acid (ArA in the figure). With DHGL/DGLA as the precursor, the PGs, TXs, and PGIs will be of 1 series and LTs of the 3 series; with EPA as the precursor, the PGs, TXs, and PGIs will be of 3 series and LTs of 5 series. (Courtesy of Vishwanath M. Sardesai, PhD)

EPA. Therefore, eicosanoids derived from AA dominate over those from other 2 precursors [24]. All cells except erythrocytes are able to produce one or more types of eicosanoids. They are not stored within cells but are synthesized as required and rapidly inactivated. Classic eicosanoids include prostaglandins (PG), thromboxanes (TX), prostacyclins (PGI), and leukotrienes (LT).

Perturbation of the cell membrane by mechanical, trauma, clinical, or other stimuli activates phospholipase A_2, a membrane-bound enzyme that is found in virtually every cell type and organ in the body, and liberates the precursor fatty acid from phospholipids. This step appears to be rate-limiting because the free fatty acid is readily converted to PGs and other eicosanoids. The synthesis is carried out by a membrane-bound PG synthetase complex which has two components: the cyclooxygenase component converts fatty acid to PGG, and the peroxidase component quickly converts PGG to PGH (Fig. 10.3).

The enzyme cyclooxygenase converts AA to PGH_2. During this process, two double bonds of the precursor fatty acid are lost, and the product has two double bonds (if the precursor is AA). The subscripts 1, 2, and 3 refer to the double bonds of the product. If the precursors were DHGL/DGLA and EPA, the products would be PGH_1 and PGH_3, respectively. Once formed, PGH is acted upon by a series of enzymes to produce PGs, TXs, and PGIs. PGH is converted to several PGs by individual isomerases which are found in all tissues, but some cells are highly selective in the metabolism of PGH.

PGs play important roles in several aspects of human physiology. They regulate a wide variety of processes including stomach secretion, uterus contraction, reproduction, blood pressure control, central nervous system, and inflammation.

In platelets, the principal product is TXA_2 which is formed by the action of TX synthetase on PGH_2 [25]. TXA_2 stimulates platelet aggregation and is also a potent vasoconstrictor. The product formed from PGH_1 is TXA_1, but is not of much significance because PGH_1 is a poor substrate for the enzyme. TXA_3 formed from PGH_3 is less potent as a vasoconstrictor than TXA_2 and has little platelet aggregating ability.

In endothelial cells, PGH_2 is converted to PGI_2 by the action of prostacyclin synthetase. It has an action dramatically opposite of TXA_2. It inhibits platelet aggregation and is a powerful vasodilator. PGH_1 does not have the Δ_5 double bond and therefore cannot be converted to PGI_1. PGI_3 formed from PGH_3 has actions similar to those of PGI_2.

Arachidonic acid can be converted to LTB_4, and cysteine-containing LTC_4, LTD_4, and LTE_4 by the action of 5-lipoxygenase followed by other enzymes. LTB_4 is a potent chemotactic agent attracting neutrophils and macrophages and causing aggregation at sites of infection or injury. LTB_3 produced from DHGL/DGLA has action similar to LTB_4 and is equally potent in its biological activity. The LTE_5 formed from EPA is 10- to 100-fold less active than LTB_4. The cysteinyl LTs are potent vasoconstrictors and bronchoconstrictors. They increase permeability in postcapillary venules and stimulate mucus secretion.

In addition to these classical eicosanoids, there are others produced by different pathways. The products include lipoxins and others with different properties.

Sometimes it becomes necessary to decrease or eliminate the formation of inflammatory eicosanoids. A number of compounds are known to interact at one or more of the many steps involved in the formation of eicosanoids. The steroidal anti-inflammatory agents, corticosteroids, inhibit phospholipase A_2 and block the release of PUFA from membrane

phospholipids. This prevents the formation of all eicosanoids. Several synthetic corticosteroids have been developed and are used clinically. Drugs blocking prostanoid synthesis are usually preferred over the more powerful steroids because of their undesirable systemic effects. The nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen are potent inhibitors of cyclooxygenase. These drugs block the synthesis of PGG and hence of PGs, TXs, and PGIs. The NSAIDs have been used to reduce inflammation, pain, and fever as well as platelet stickiness in an effort to reduce the risk of CHD. Aspirin (low doses) is one of the most important and cost-effective drugs for arthritis and for the secondary prevention of CHD. It reduces the rate of arterial thrombotic events in high risk patients by at least 25%. Recent available research data of aspirin's use for primary prevention for high-risk CVD patients is showing a modest benefit. Recommendations are that future aspirin studies consider the extent of benefit–risk for healthy individuals that possibly can be partially counterbalanced by the risks [26, 27].

Dietary intake determines to a great extent the fatty acid composition of phospholipids in the plasma and cell membranes. The eicosanoids derived from AA are, in general, pro-inflammatory, while those derived from DHGL/DGLA and EPA are less inflammatory or anti-inflammatory. EPA can be increased by consuming fish regularly or taking fish oil supplements. DHGL/DGLA can be increased by taking borage oil, which is rich in gamma linolenic acid. It increases DHGL/DGLA which forms PGE_1, a potent antagonist to inflammatory PGE_2. There are several dietary constituents that can modulate the accumulation of PUFA in tissues and/or control the eicosanoid production.

10.4.2.6 Specific Role of W_3 Fatty Acids

ALA is not known to have any specific functions other than to serve as a precursor of EPA and DHA. Biological structures involved in fast movement or signal transmission appear to have a requirement for the highly unsaturated fatty acid DHA. This measure is important for visual and neurological development. In several species, including humans, the retinal rod outer segment disk membrane in which rhodopsin rests, the major phospholipid contains 40–60% of the total fatty acid as DHA. The retina conserves and recycles DHA even when fatty acid intake is low. It is required for normal development and function of the retina. The phospholipids of the brain gray matter contain high proportion of DHA, suggesting it may be important in central nervous system function. Brain DHA content may be particularly important because animal studies have shown that depletion of DHA in the brain can result in learning deficits.

10.4.3 Deficiency

Animal experiments have shown that the young are more susceptible to EFA deficiency than adults. Deficiency in humans is rare because most diets contain adequate EFA to meet the daily requirement. Because adipose tissue lipids in free-living healthy adults contain about 10% of total fatty acids as LA, biochemical and clinical signs of deficiency do not appear during dietary fat restriction or malabsorption when they are accompanied by an energy deficit. In this situation, release of LA and small amounts of AA from adipose tissue reserves may prevent development of EFA deficiency. Young, especially low-birth weight infants have limited body stores of EPA and are more susceptible to deficiency. Cow's milk has only 25% of the LA contained in human milk, but when ingested in normal amounts, it has enough LA to prevent deficiency. Babies fed formula low in LA, such as a skim milk formula, can develop deficiency [28].

In human infants, the deficiency signs include dermatitis, rough and scaly skin, unsatisfactory growth, and impaired water balance. The skin symptoms and water loss are both examples of a general derangement of membrane structure and consequent function [29]. Erythrocytes become more fragile and susceptible to osmotic hemolysis. There is elevated triene/tetraene ratio above 0.2. The most common cause of EFA deficiency in humans of all ages is the long-term intake of fat-free parenteral nutrition (PN). It is commonly administered as a continuous infusion of a glucose-containing solution, which results in a constant elevation of serum insulin. This depresses the release of fat from adipose stores, which in normal adults have a little more than 1000 g of EFA, enough to otherwise sustain dietary needs for more than 6 months. Because of the block in the release of EFA, continuous fat-free PN seems to provide optimal conditions for the development of deficiency [30]. In these patients, plasma-free fatty acids are derived from glucose and these do not include EFA. Glucose-free PN containing only amino acids and fat does not produce EFA deficiency.

Studies in infants maintained on long-term fat-free PN showed development of clinical signs together with biochemical evidence of deficiency (high triene/tetraene ratio). Some premature infants developed very rapid clinical signs and biochemical changes in plasma starting on the second and third day of life. Limited stores of EFA characteristic of the premature state and high caloric expenditure might have been responsible for the early development of deficiency. In the neonate, signs of deficiency may become apparent in 5–10 days on fat-free PN, whereas in adults, the biochemical evidence of deficiency may be seen by the end of 2 weeks after initiation of PN and by the end of 7 weeks; all patients exhibit clinical signs of deficiency. Manifestations of deficiency in these patients include alopecia, brittle nails, dermatitis, increased capillary fragility, indolent wound healing, and increased susceptibility to infection. Administration of diets containing LA reverses both clinical and biochemical abnormalities. To correct or prevent the deficiency when oral intake is denied, LA must be provided intravenously. The minimum LA dose to prevent deficiency state is about 5% of the total calories for adults and 2% for pediatric patients. Deficiency is accelerated by the increased metabolic demands associated with growth and hypermetabolism following injury, sepsis, or stress. These patients should receive 500 ml of 10% lipid emulsion 2–3 times per week.

The first case involving ALA deficiency was described in 1982. A young girl was maintained on PN-containing safflower oil emulsion rich in LA and poor in ALA. After 3 months, she developed visual problems and sensory neuropathy [31]. Serum analysis revealed very low levels of ALA and PUFA derived from it. PN was then changed to include soybean oil, which contains both LA and ALA. Within 3 months, all the symptoms of deficiency were resolved. Since then several other cases involving ALA deficiency have been reported [32, 33].

W_3 PUFA are low in children with attention-deficit hyperactivity disorder (ADHD) compared with other children. Patients with Zellweger syndrome have lower levels of DHA in the brain, retina, and erythrocytes. Recent studies show a correlation between low levels of DHA and certain behavioral and neurological conditions associated with aging, such as dementia, depression, memory loss, and visual problems.

10.4.4 Requirements

The exact requirement of EFA in humans is not clearly defined [34]. Clinical signs of EFA deficiency are generally found only in patients on PN and without a source of PUFA. The plasma triene/tetraene ratio is below 0.2 when dietary EFA are adequate and is increased above 0.2 in relation to the degree of deficiency. The optimum dietary LA required to give a ratio of less than 0.2 and to prevent symptoms of EFA deficiency is 1–2% of total calories. It has been suggested that those functions dependent on eicosanoid formation may show an optimum response with dietary LA at higher levels perhaps as high as 6–10% of total calories. An absolute amount required is not yet known, but because no ill effects have been reported up to this level, the tendency is to consider it as optimal. The average daily intake of LA by adults in most industrialized western countries is about 10 g. The recommended adequate intake is 17 g for young men and 12 g for young women. The quantitative requirement for ALA in humans is not known. Biochemical changes of W_3 fatty acid deficiency include a decrease in plasma and tissue DHA concentrations. There are no accepted cut-off concentrations of plasma or tissue DHA below which functions attributed to W_3 fatty acids, such as visual or neural functions, are impaired. However, on the basis of its derived products found in the blood of patients maintained on PN, it has been suggested that ALA requirement should be between 0.2% and 0.3% of total calories. The recommended adequate intake is 1.6 and 1.2 g per day for men and women, respectively.

In pregnancy, the accumulation of EFA is estimated to be about 620 g, which includes the demand for uterine, placenta, mammary gland, and fetal growth and the increased maternal blood volume. To meet these needs, 4.3% of the accepted calorie intake in the form of EFA is recommended during pregnancy. Approximately 4–5% of total energy in human milk is present as LA and ALA and 1% as long-chain PUFA derived from these acids amounting to about 6% of total energy as EFA and its metabolites. The fat stored during normal pregnancy is utilized during lactation at the rate of about 300 calories per day. Between 3 and 5 g of EFA are secreted in milk per day [35]. An additional 1% and 2% of energy in the form of EFA is recommended during the first 3 months of lactation, and an additional 2% and 4% of the energy above the basic requirements is recommended thereafter. The adequate intake for LA is set at 13 g per day and for ALA 1.3 g per day. For infants, the adequate level for LA is 4.4 g per day, and ALA is 0.5 g per day based on the average amount of LA provided by human milk. Human milk contains long-chain fatty acids including AA and DHA. Normal growth of infants depends on an adequate supply of EFA. The formula milk should have EFA, including AA and DHA similar to those found in human milk.

10.4.5 W_3 Fatty Acids and Health

The tissues of the body require W_3 PUFA for their proper functioning just as they need W_6 PUFA. The importance of W_3 PUFA is their likely role in the prevention of many chronic diseases, now rampant in our society [36]. These especially include CHD and even cancer. EPA and DHA have been assumed to reduce the risk of CHD and stroke by a multitude of mechanisms by preventing arrhythmias, reducing atherosclerosis, decreasing platelet aggregation, lowering plasma triglyceride concentrations, decreasing proinflammatory eicosanoids, and decreasing blood pressure in hypertensive individuals.

Many epidemiologic studies have used fish and fish oil intake as surrogates for W_3 fatty acids intake because of their high content of EPA and DHA found in fish. People who follow a Mediterranean diet are less likely to develop heart disease. The diet emphasizes foods that are rich in W_3 fatty acids. Alaska natives who get high amounts of W_3 fatty acids from eating daily fish also tend to have lower incidence of heart disease. The ratio of LA/ALA is important in the diet because LA and ALA compete for the same desaturase enzyme [37]. Thus, high ratio can inhibit conversion of ALA to DHA, while a low ratio inhibits conversion of LA to AA.

Clinical and epidemiological studies have addressed the W_6/W_3 fatty acid ratio with respect to the beneficial effects on the risk of certain diseases associated with W_3 fatty acids, including EPA and DHA [38]. Low rates of heart disease in Japan compared with the United States have been attributed, in part, to a total W_6/W_3 fatty acid ratio of 4:1 with about 5% energy as LA, 0.6% energy from ALA, and 2% energy from EPA + DHA in Japan, compared with intakes of 6% energy from LA, 0.7% energy from ALA, and less than 0.1% from EPA plus DHA in the United States. Similarly, an inverse association between the dietary total W_6/W_3 fatty acid ratio and cardiovascular disease, cancer, and all-cause mortality as well as between fish intake and CHD mortality has been

reported. Based on studies in animals, children, and adults, a reasonable LA/ALA ratio of 5:1 to 10:1 has been recommended for adults.

Two recent studies show that people who eat substantial amounts of fish are greatly protected from sudden unexpected death caused by severely abnormal heart rhythms [39]. In the Physicians' Health Study, 22,000 men were divided in four groups based on the concentrations of W_3 fatty acids in blood. The men in the highest quartile had 81% lower risk of sudden death than those in the lowest quartile during a 17-year period of observation [40]. In the Nurses' Health Study, investigators used dietary information gathered in five interviews between 1980 and 1994 to estimate the fish intake of 85,000 female nurses. Those who ate fish once a week had a 30% lower risk of heart attack or death than those who never ate fish, and those who ate fish 5 times a week had a 34% lower risk. The data also indicated that similar to the mortality from CHD, all-cause mortality was lowest among groups of women who ate the most fish [41].

Results of these studies indicate that even in people with no history of CHD, high blood W_3 fatty acid levels can lower their risk of CHD death. The link to arrhythmias is the most substantiated [42], but fish oils also have other heart-friendly effects, such as lowering the levels of triglycerides in blood, reducing inflammation, slowing coronary artery thickening, and reducing the tendency of blood to clot.

It has been proposed that omega-3 index be used as a biomarker for cardiovascular disease risk [43]. The index is defined as the amount of EPA + DHA in red blood cell (RBC) membranes expressed as the percent of total RBC membrane fatty acids. The EPA + DHA content of RBCs correlates with that of cardiac muscle cell, and several observational studies indicate that a lower omega-3 index is associated with increased risk of CHD mortality [44]. The proposed zones being used are high risk <4%, intermediate risk 4–8%, and low risk >8%. Supplementation with fish oil capsules for a few months increases the omega-3 index.

The American Heart Association recommends that healthy adults, especially those at higher risk for heart disease, eat a variety of fish, preferably oily fish such as salmon, mackerel, and sardines, at least twice a week [45]. The association also recommends increasing the intake of ALA-rich foods such as walnuts, flax seeds, and canola and soybean oil. In September 2004, the US Food and Drug Administration (FDA) allowed the following "qualified" health claim for certain foods containing fish oils: "Supportive but not conclusive research shows that consumption of EPA and DHA W_3 fatty acids may reduce the risk of coronary heart disease" [46]. The FDA action marks the second time the agency has allowed a qualified health claim for a conventional food product: early the same year, the agency granted a claim linking walnuts and certain other nuts to a reduction in heart disease risk.

Oily fish and fish oil consumption have been associated with protection against the development of some types of cancer, such as colorectal, mammary, and prostate cancer [47]. A study has shown that consumption of fish constituting at least a moderate part of the diet significantly lowers the risk of prostate cancer. EPA and DHA have been shown to suppress neoplastic transformation, inhibit cell growth and proliferation, induce apoptosis, and inhibit angiogenesis by suppressing omega-3-derived eicosanoid products.

Several studies have reported a negative relationship between PUFA intake and risk of diabetes. Fish intake has specifically been reported to have a negative association. Rheumatoid arthritis (RA) is an autosomal disease that causes inflammation of joints. Fish oils have been found to reduce symptoms of RA, including joint pain and morning stiffness. People with RA who take ALA may be able to reduce their dose of anti-inflammatory drugs. Fish oil also may help people with osteoarthritis. One study in rats has suggested that diets containing omega-3 fatty acids lead to lower levels of fat accumulation compared with diets containing other fatty acids.

Population studies in Chicago have reported that people 65 and older who ate fish at least once weekly were 60% less likely to develop Alzheimer's disease than those who never or rarely ate fish [48]. Depression is associated with lower levels of W_3 fatty acids in RBC membranes. Countries with the highest rates of depression ate the least amount of fish while those with the lowest rates of depression ate the most fish [49, 50]. W_3 fatty acids may also protect the eyes. In one study, it has been reported that those who ate fish twice a week had a 36% lower risk of macular degeneration, the leading cause of blindness in old age [51].

There are also data suggesting W_3 fatty acids may be helpful for a raft of other ills such as hypertension, aggression, attention deficit disorder, autoimmune diseases, and several other diseases [52, 53]. Fish and fish oil thus qualify as functional foods.

Fish such as salmon and tuna are considered as optimal dietary sources of omega-3 fatty acids. The acceptable daily intake of these fatty acids is 1.6 g for men and 1.1 g for women, although more may be recommended for certain conditions such as heart disease and arthritis. Fish contain mercury and other unsafe pollutants which may limit the amount of fish that should be consumed, particularly for children and women who are pregnant or breastfeeding. Mercury is a known toxin for the human nervous system and is linked to learning and behavioral problems in children [54]. In adults, mercury can cause memory loss and other health problems. For those who do not eat fish, a fish oil supplement may be considered. The best fish oil supplements contain 1 g per capsule, which provides 440 mg of W_3 fatty acids. The most common fish oil capsules in the USA provide 180 mg of EPA and 120 mg of DHA. The recommended dosage is 1–2 capsules a day for adults. Large doses may exert a dose-related effect on lowering bleeding time.

With the increasing popularity of the vegetable diet and mounting focus on mercury and other contaminants in seafood, flaxseed oil which contains ALA has become a safer choice. We can make EPA and DHA from ALA, but the process is slow. Researchers at Dow AgroSciences inserted

the algae genes required to make DHA into canola seeds. The enzyme that these genes produce allows the canola plant to synthesize the DHA from ALA [55]. Such plants produce canola oil that is enriched with DHA. Monsanto genetically engineered a soybean plant to produce W_3-derived products in soybean oil.

10.4.6 Food Sources

The most prevalent source of W_6 fatty acids is LA. It is present in almost all vegetable oils such as safflower oil, corn oil, sunflower oil, and soybean oil. Common fatty acids found in most land plants are generally not elongated above the 18-carbon level. Borage seed oil is the richest source of γ-linolenic acid (GLA) among vegetable oils. It contains 24% of GLA. Black currant is the next with 17% and evening primrose contains 8% of GLA. This fatty acid is an intermediate in the conversion of LA to AA. Dietary meat, poultry, and eggs provide small amounts of AA. The W_6 PUFA intake in the USA ranges from 12 to 17 g per day in men and 9–11 g per day in women. It accounts for 5–7% of total energy intake in diets of adults. Most W_6 PUFA (80–90%) are consumed in the form of LA. Others such as AA and GLA are in small amounts in the diets.

The major sources of W_3 fatty acids as ALA include vegetable oils such as soybean, canola, and flaxseed oil. Flaxseed is the rich source containing 50–60% ALA. Table 10.3 shows the linolenic acid content of some foods.

Leafy vegetables, such as spinach, kale, and romaine lettuce, contain small amounts. Fish oils provide a mixture of EPA and DHA, and fatty fish are the major dietary sources of EPA and DHA. Table 10.4 shows the content of EPA and DHA in some types of fish.

The intake of total omega-3 fatty acids in the United States is about 1.6 g per day (0.7% of energy intake), and of this, ALA accounts for 1.4 g/day and only 0.1–0.2 g/day of EPA and DHA.

Table 10.3 Selected food sources of ALA

Source	Serving size	Content in grams
Canola oil	1 tablespoon	1.30
Walnut oil	1 tablespoon	1.40
Flaxseed oil	1 tablespoon	7.48
Soybean oil	1 tablespoon	0.90
Flaxseed ground	1 tablespoon	7.48
Walnuts	1 ounce	2.60
Chia seeds	1 ounce	4.90
Soybeans	1 ounce	0.47
Hickory nuts	1 ounce	0.29

Table 10.4 Selected food sources of EPA and DHA content in grams

Source	Serving size (ounce)	EPA (g)	DHA (g)
Herring	3	1.06	0.75
Salmon	3	0.86	0.62
Sardines	3	0.45	0.74
Crab	3	0.24	0.10
Oysters	3	0.75	0.93
Tuna	3	0.40	0.44
Trout	3	0.45	0.74
Mackerel	3	0.43	0.59
Shrimp	3	0.07	0.10
Flounder	3	0.24	0.25

10.5 *Trans*-Fatty Acids

Due to fermentation in ruminant animals such as cows, small amounts of *trans*-fatty acids exist naturally in meat and dairy products. This was the source of *trans*-fatty acids in diets of humans until the beginning of the last century.

After the introduction of Crisco in 1911, partially hydrogenated fat was used to make margarine and numerous other products, including crackers, cookies, and other baked goods and fried snacks such as potato chips. Food manufacturers started using partially hydrogenated fats because of their favorable properties, such as longer shelf life, stability during frying, and palatability. Consumers preferred these products (usually considered to be "cholesterol-free" and high in PUFA) to lower cholesterol intake, theoretically reducing the risk of CHD. The consumption of these products continued to increase steadily [56].

Trans-fatty acids account for 3–8% of the fat in the American diet or 8.3–13.5 g per day. However, the intake may be much higher for persons consuming large amounts of commercially baked products and fried foods. A medium-size helping of French fries contains 5–6 g, a doughnut contains 2 g, and an ounce of crackers 2 g of *trans*-fatty acids.

Prior to 1980, there was generally no concern about the trend toward increased consumption of hydrogenated fat in the US diet, especially because it displaced fat relatively high in saturated fat. In the 1980s, studies showed hypercholesterolemic effects of *trans*-fatty acids in rabbits. Several studies in humans reported that a diet enriched with *trans*-fatty acids caused blood LDL cholesterol to increase and HDL cholesterol to decrease, resulting in less favorable total cholesterol/HDL ratio to increase [57]. Two studies also showed a rise in plasma lipoprotein(a) with relatively high consumption of *trans*-fatty acids. Similar to LDL, the concentration of lipoprotein(a) in plasma is directly associated with increased risk for CHD.

On a per calorie basis, *trans*-fatty acids currently appear to increase the risk of CHD more than any other macronutrient at low levels of consumption (1–3% of energy intake). The major evidence came from the Nurses' Health Study (NHS) – a cohort study that has been following approximately 120,000 female nurses since its inception in 1976. Researchers analyzed data from 900 coronary events from the NHS population during 14 years of follow-up and determined that a nurse's CHD risk roughly doubled for each 2% increase in *trans*-fat calories consumed (instead of carbohydrate calories). By contrast, it took a more than 15% increase in saturated fat calories (instead of carbohydrate calories) to produce a similar increase in risk. *Trans*-fatty acids behaved similar to saturated fatty acids by increasing plasma LDL cholesterol, but unlike saturated fat, it had the additional effect of lowering plasma HDL cholesterol levels [58]. Other adverse effects reported were on growth and development, inhibition of conversion of LA and ALA to AA and DHA, respectively, possible association with Alzheimer's disease, and increase in weight gain [59].

In recent years, a series of studies has provided unequivocal evidence that *trans*-fat adversely affects health [60]. In 2003, Denmark became the first country to ban *trans*-fat. Many other countries followed suit. In the United States, New York City passed such a ban in restaurants in 2006 and California did the same in 2008.

The US Food and Drug Administration addressed this issue by requiring disclosure of the *trans*-fat content in food in Nutrition Labels, beginning in 2006. On March 16, 2015, the FDA took further action that will significantly reduce the use of partially hydrogenated oils, the major source of artificial *trans*-fat in the food supply [61]. The FDA is providing the companies 3 years to either reformulate products without partially hydrogenated oils and/or petition FDA to permit specific uses. Food companies have already been working to remove partially hydrogenated oils from processed foods, and FDA anticipates that many may eliminate them ahead of the three-year compliance date. This action is expected to reduce cardiovascular disease risk. The Centers for Disease Control and Prevention estimates that this action could prevent as many as 20,000 coronary events and 7000 deaths from coronary causes each year in the USA.

10.6 Conjugated Fatty Acids

Conjugated linoleic acid (CLA) represents a collective term for a group of geometric and positional isomers of LA that contain a conjugated double bond system instead of the isolated double bonds. It has attracted a fair amount of attention and has been reported to have different biological effects in health-related disorders [62].

CLA is beneficial in lowering body fat while preserving muscle tissue. Individuals who took 3.2 g CLA per day had a drop in fat mass of about 0.2 lb. each week (i.e., about 1 lb. a month) compared with those given a placebo. Some studies indicate CLA has potent beneficial effects as antitumor, antiobesity, antiatherogenic, and antidiabetic activities. The molecules have been shown to modulate immune function mainly in animals and in in vitro studies [63].

Small amounts of CLA are present in all diets. It is usually found in beef and dairy products. The best sources of CLA are from grass-fed cattle and its products. The average intake in the USA is in the range of 151 to 212 mg/day. CLA is marketed in dietary supplement form for its anticancer benefit, for which there is some evidence, but no known mechanism, and as a body building aid. Despite the many claims made, good evidence of human health benefits remains scarce.

10.7 Conclusions

Fatty acids are integral components of the lipid macronutrients that have four major physiological roles. First, fatty acids are fuel molecules stored as triacylglycerols, or triglycerides, that have a neutral charge mainly stored in adipose tissue in adipocyte cells. The triacylglycerols are oxidized and able to provide energy needs of the cells or tissues. Second, fatty acids function as the base unit of phospholipids and glycolipids, colluding with cholesterol responsible for modulating cell membrane fluidity (see ▶ Chap. 22). These amphipathic molecules are important components of all the biological bilayer membranes that allow for highly selective permeability barriers. Membrane processes such as transport and cell sensing depend of the fluidity of the membrane modulated by cholesterol (see ▶ Chap. 12). Dietary intake of fats and cholesterol are primary determinants of the structure and composition of the membranes affecting their function. Third, fatty acids by a covalent attachment can modify proteins to position the location of the protein on the membrane structure. Specific proteins involved with mediating membrane functions such as energy transduction, transport, and cell-sensing communication. The fourth role of fatty acids is their synthesis to derivatives that serve as hormones and intracellular messengers. Fatty acids and their role in human metabolism are presented in this chapter to provide the science and principles for which the nutrition practitioner can guide disease management for assessment of an individual's fatty acid status and develop therapeutic interventions toward restoring optimal function (see ▶ Chap. 11).

Acknowledgments I wish to gratefully acknowledge the secretarial assistance of Cindy Luiz in the preparation of this manuscript. I also wish to thank Amie Dozier, Associate Director, Medical Education Support Group of the School, for preparing the illustrations and Cynthia Washell, Practice Administrator, Department of Surgery, for providing support.

2. Nutritional Influences on Composition and Function
3. Tools of the Trade for Lipid Therapy
4. Case Reviews

11.1 Introduction

The main global healthcare concern of the twenty-first century is chronic disease. Public health leaders around the world are working to quell the unsustainable widespread changing phenotype of populations. In the United States, more than two-thirds of the citizens are currently overweight or obese, and the trend is increasing. In 2012, there began an unprecedented decline in U.S. lifespan. Much of the trend toward chronic disease is due to dysfunction in the underlying mechanisms of cell signaling and the messages that operate at the organelle and cell membrane sites. This is where the DNA is expressed and put into action as body systems read the environment and determine how to respond to survive.

IFMNT is a person-centered approach with each individual assessed, and interventions developed, as personalized therapy based on the nutrition and medical data that is gathered during a comprehensive evaluation. For population of persons with the same diagnosis, there will be an equal number of uniquely designed protocols. Each disease has many causes, thus this chapter does not give a recipe for diagnosis and intervention rather provides principles and tools to draw from to form the best protocol to restore wellness.

In this chapter, we first examine the structure of the cell membrane, which is comprised of different regions of *microdomains* referred to as *membrane rafts* with varying percent lipids (e.g., fats, phospholipids, steroids), which are mainly formed from the food fats and oils we eat [1]. The structure of membranes determines the function of the "control tower" of our systems where communication and cell signaling occurs. Second, we assess function and how well the body can manage all its systems to enable them to produce a healthy organism. The evidence that the lipids we eat create the composition of our lipid structures and control our function is mounting in recognition of the metabolic plasticity of human metabolism [2, 3] (see ▶ Chap. 10). At the time of this publication, there is public and scientific interest in the comparison of the effects of high carbohydrate, low fat diets to those with low carbohydrates and high fat. The main thrust of this latter diet protocol is exchange of carbohydrates for fats. Nutrition professionals need to be aware of the metabolic implications of this dietary change and the science behind what is often referred to as paleo or ketogenic (keto) diets (see ▶ Chap. 23).

This chapter addresses emerging evidence about fatty acid metabolism and outdated misinformation that is still accepted dogma regarding dietary fat. Understandably, the public and even nutrition professionals are confused about dietary fats. We are on the brink of a new understanding of the science of lipids, food processing, and how one's unique personal genetics determine the type and amount of fats that may benefit an individual.

Table 11.1 Integrative and functional medicine principles

Focuses on patient/client-centered approach
Acknowledges biochemical uniqueness of each individual
Patient practitioner partnership
Appropriately uses conventional and complementary treatments
Considers genetic, environmental, and lifestyle factors
Seeks balance between mind, body, and spirit
Acknowledges all body systems are interconnected by physiological and metabolic factors
Identifies health as a positive vitality
Uses natural, effective, less invasive interventions, when possible

The goal of this chapter is to help the nutrition-trained professional understand the molecular structure of an individual's cellular membranes and how those structures affect the efficiency and proper functioning of metabolism. With that knowledge, one has the clinical skills in medical nutrition therapy for assessment and intervention. The practitioner must have working knowledge of foods and supplements, which support the body's *metabolic plasticity*. This approach is viewed through the lens of *systems biology*, which is the science of all systems interacting and influencing each other to produce the phenotype of an individual; it is often referred to as integrative and/or functional medicine (see Table 11.1).

11.2 History of Dietary Fat

It can be enlightening to think back on historical diets and events that led to the current recommendations about fat. Around the 1950s, recommendations to Americans concerning fat were promoted by publications from Gofman [3] and Keys (1953) [4], in which the dogma was propagated that "saturated fat and cholesterol were bad." A connection was made with respect to the rise of heart disease and epidemiologic correlations between dietary saturated fat, cholesterol and heart disease. Not much has changed in the last 70 years in recommendations to reduce total fat, saturated fat, and cholesterol-rich foods. Until the 1940s in the United States, heart disease and cancer were minor contributors to mortality statistics, but they have continued to grow to the number-one and -two causes of death in industrialized countries.

11.2.1 Human History

Fats used for dietary ingestion were "all natural" (not processed) prior to ~1900. Lipids, oils, and fats commonly used were:

- Fat or oil-rich foods
  - Meat
  - Poultry and skin
  - Fish, shellfish, roe
  - Egg yolk
  - Olives, olive oil
  - Other plants: nuts, seeds, avocado
  - Essential and/or medicinal oils
- Cooking oils
  - Butter, ghee
  - Lard
  - Tallow
  - Coconut oil
  - Olive oil, foot-pressed

The nutrition transition to the standard American diet (SAD) [5] at the beginning of the twentieth century paralleled the increase in the onset and progression of chronic human diseases as the food supply changed in quality and quantity, giving rise to obesity and a mismatch of gene–diet interactions. Cooking oils intolerant to heat, processed foods containing trans fats, and damaged oils have become commonplace. There is currently a debate regarding the impact of the increase in omega-6 on human health [6] and newer processing methods in the food oil industry that are allowing "damaged" oils and "new-to-nature" forms of oils into the food supply (e.g., hydrogenated vegetable oils, high heat processing of vegetable oils, changing proportion of linoleic acid, and monounsaturated fats to "high oleic" vegetable oils). Issues that need to be addressed include the influence of ingested food oils on the structure and function of cellular health and how these food oil changes have contributed to the epidemic of chronic disease?

11.2.2 The Nutrition Transition of Oils and Fats in the Early 20th Century

Processed oils:
- Heat-processed vegetable oil
- High heated commercial oil used for deep frying
- Hydrogenation of vegetable oils
- Charred red meats or high-temp-oil deep frying produce trans fats or acrylamides

Specialty foods available after 1950:
- *Natural*: nitrogen-packed seed/nut oils, refrigerated
  - Sunflower, safflower, flax (refrigerated), avocado oil, flax–safflower oil 4:1, macadamia oil
- Processed:
  - Deep frying with vegetable oils
  - Hydrogenated or partially hydrogenated vegetable oils

The ratio between the types of fats has changed dramatically during the past 70–100 years with a three-fold increase in dietary levels of the omega-6 (n-6) 18 carbon (C18), polyunsaturated fatty acids (PUFA), linoleic acid (LA; 18:2n-6) [5]. Horrobin [6] proposed an ideal ω6:ω3 ratio of 4:1, and most fatty-acid scientists agree optimum ratio somewhere with the range of 1:1 to 5:1 ratios [7, 8].

Chronic diseases are characterized as long-latency lifestyle and diet-related. Chronic diseases all have inflammatory pathophysiology promoted by injury, infection, or biological stressors (e.g., chronic inflammation, high visceral adiposity, emotional stress). For example, an acute infection may either be resolved by a healthy immune system or survive and continue as a subclinical infection that is often not recognized but continues to wear on the immune system. Lipids that participate in eicosanoid metabolism are largely responsible for control of inflammation and the ability of the metabolic resolution of an inflammatory event.

The healthy human body is equipped with defense features from conception throughout life to interact with the environment to protect it from infection and injury. All of the barriers' defensive functions are a reflection of their lipid-dominant structure. Much of the defense starts with the lipid-rich skin barrier and microbiome at all body orifices to protect from pathogens entering and infecting or causing injury.

11.3 The Lipidome and Clinical Application

The application of lipidomics in clinical practice is an important new tool for the healthcare practitioner due to expanding knowledge of the structural and functional properties of fat. Dietary fat is a key topic in government food policy, research, public media, and in the homes of families preparing food during a period of dramatic change in thinking about how we incorporate fat into diets. Many people feel confused about the amount and types of fat to eat. Is saturated fat bad? Is a low-fat diet good? Dietitians and healthcare professionals are beginning to learn about the emerging science of lipidomics and how that applies to the science of lipid metabolism and the use of dietary and food supplement to maintain health.

Lipids are highly diverse molecules that are as important for life as proteins and genes [2] with critical roles in membrane structure, cell signaling, energy storage, inflammation regulation, and as base units for constructing messenger hormones. Maintaining lipid balance and homeostasis is within a practitioner's capability when they are skilled at recognizing lipid imbalances and their relationship to disease pathology. One of the profound roles of lipid metabolism involves metabolic regulation of inflammation. It is essential to understand how to modulate lipid metabolism considering that the global epidemic of chronic disease in healthcare reflects prolonged and unresolved inflammation. All the "ingredients" of lipids (fatty acids, phospholipids, sterols, sphingolipids) and the associated enzymes and nutrient cofactors affect the control and resolution of inflammation. Knowledge of lipid modulation by dietary and lifestyle changes is a powerful addition to the toolbox of the IFMNT practitioner.

The two functions of the lipids that can be modulated by nutrition therapy are membrane structure and inflammation control.

- Membrane structure: the membrane is at least 50–75% lipids with embedded protein structures forming receptors, channels, and other structures [6] "You are what you eat." What fats and oils and sterols you eat become the structural composition of your membranes and influence their function of cell signaling, communication, and transport.
- Inflammation control: The lipid eicosanoid molecules play a key role in our survival. They are the primary metabolites teaming with the immune system to manage the immune response and control inflammation. Dysregulated lipid metabolism and nutrient status are thought to play a major role in the pathophysiology of every chronic disease. Since chronic prolonged inflammation is present in every chronic disease, the eicosanoids become priority in supporting their metabolic function. And the most effective way of modulating the eicosanoid cascade is nutrition lipid therapy guiding dietary intake of fats and oils and nutrient cofactors.

Each individual is unique. IFMNT is a person-centered approach with each individual assessed, and interventions develop as personalized therapy based on the nutrition and medical data that are gathered in the initial interview. For a population with the same diagnosis, there will be that many different protocols recommended. For one disease, there are many causes. That is why this chapter does not include specific interventions for a diagnosis but provides principles to consider and draw from in forming the best regulation of structure and inflammation control to restore wellness.

11.3.1 Clinical Imbalances

The conceptual diagram below (see Fig. 11.1) provides a guide to hearing the patient's whole story, so that an assessment can be as comprehensive as possible to narrow down root causes of the patient's condition. In seeking root causes of the etiology of a disease condition, one must investigate the health and *structural integrity* of the cell membrane. All cells in the body share the basic structure and function of a

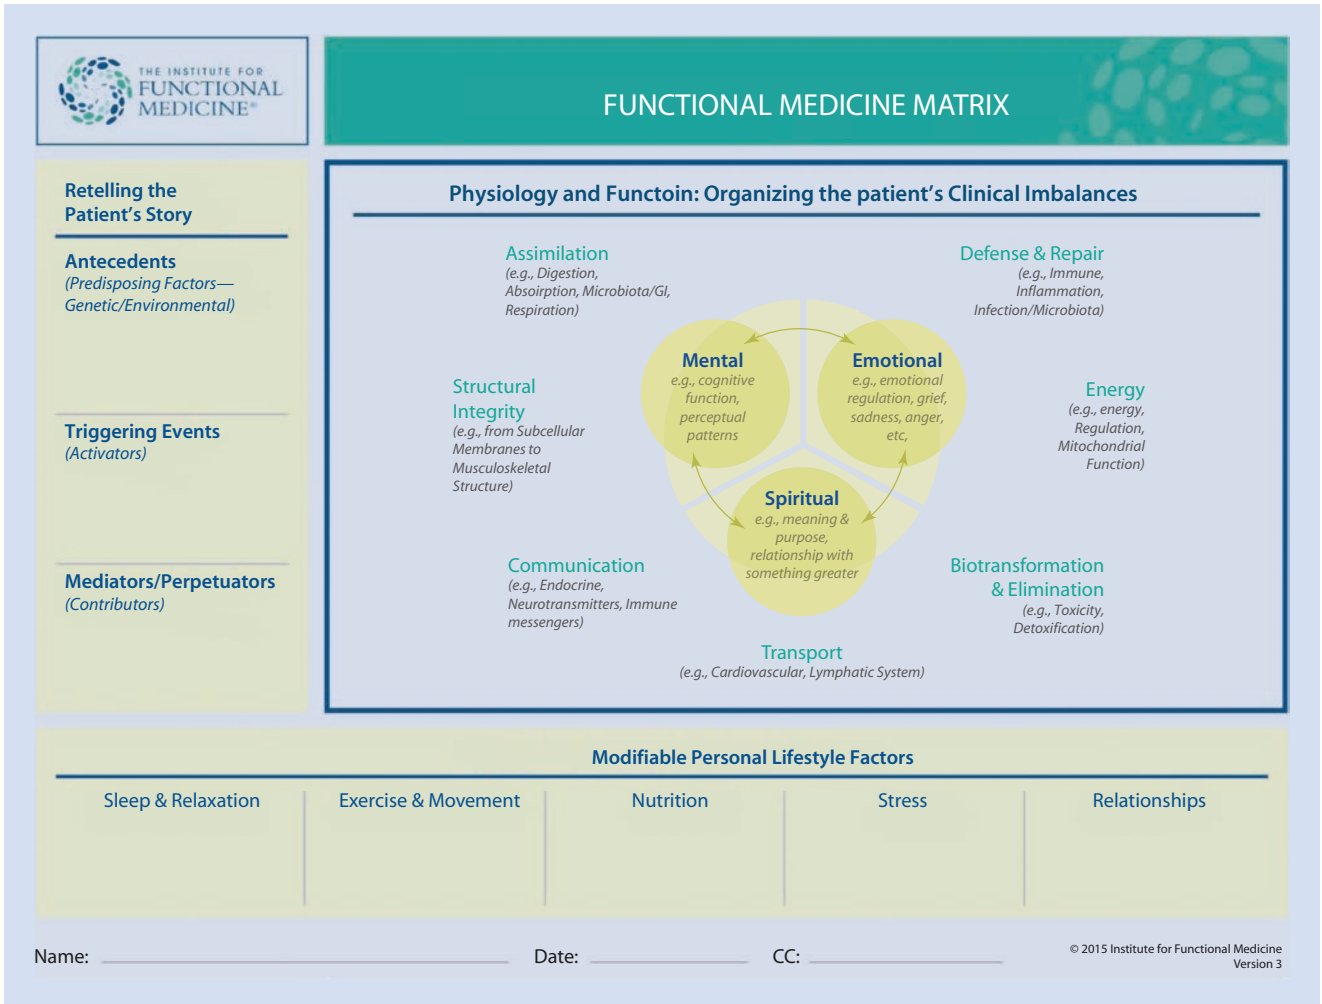

Fig. 11.1 IFM Matrix™ Conceptual diagram to guide the practitioner assessment procedure to hear the whole patient's story preparing for improved diagnosis of root causes of health issues. (Used with permission from The Institute for Functional Medicine ©2015)

bilayer membrane made of 50–75% phospholipids, fatty acids, cholesterol with embedded proteins forming channels, and receptors to facilitate ports of entry and exit to and from the intracellular to extracellular compartments. There are some carbohydrate molecules functioning as "antennas" extending from the surface of the cell for messaging and cell signaling [9, 10].

The other core physiological system to be investigated when assessing an individual's fatty acid status is *defense and repair*. Since lipids and fatty acids of the eicosanoid molecules are the primary influencers and regulators of inflammation, treatment of the defense and repair systems begins to reveal the etiology of the inflammatory aspect of an individual's condition. Once identified, utilizing the skill set of modulating lipid and fatty acid status will help target the intervention needed to restore structure, function, and wellness. The cell membrane is a primary determinant of the quality of an individual's health (see ► Chaps. 12 and 19) (◘ Fig. 11.1).

The structure and function of cells depend on membranes, which not only separate the interior of the cell from its environment but also define the internal compartments of eukaryotic cells, including the nucleus and cytoplasmic organelles. The formation of biological membranes is based on the properties of lipids, and all cell membranes share a common structural organization: bilayers of phospholipids with associated proteins. These membrane proteins are responsible for many specialized functions: some act as receptors that allow the cell to respond to external signals, some are responsible for the selective transport of molecules across the membrane, and others participate in electron transport and oxidative phosphorylation. In addition, membrane proteins control the interactions between cells of multicellular organisms. The common structural organization of membranes thus underlies a variety of biological processes and specialized membrane functions, which will be discussed in detail in later chapters [9].

11.4 Nutritional Influences on Body Composition and Function

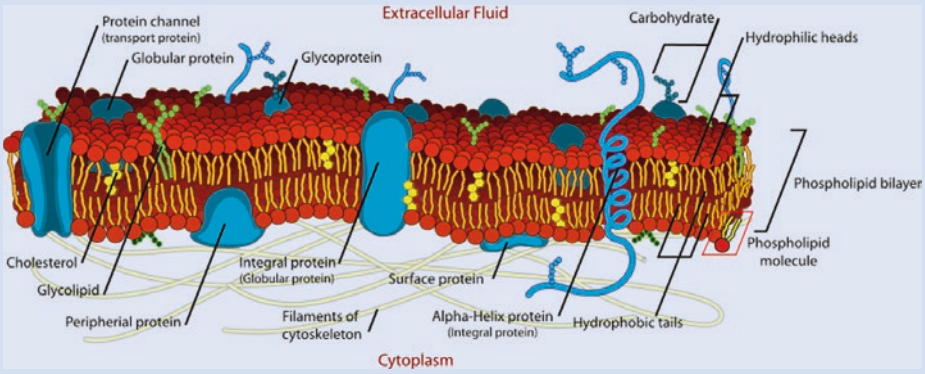
11.4.1 Structure and Functions of the Cell Membrane

11

The prevailing concept of cell membrane structure is the phospholipid bilayer that is impermeable to most water-soluble molecules, often referred to as the fluid mosaic model [9]. Most of the phospholipids in the membrane are present as a biomolecular sheet, with the fatty acid chains in the interior and exterior of the bilayer. Membrane proteins are located either on the internal or external faces of the membrane or projecting from one side to the other. An important feature of the membrane is "membrane permeability," allowing flexibility for molecules to move around [2, 11] (◘ Fig. 11.2).

The Cellular, Organelle, and Nuclear Bilayer Membranes of Each Cell [10]

- Protect and hold together each compartment.
- Protect cell compartments from their surrounding environment.
- Control movement of substances transported in and out of the cell.
- Manage immune responses regarding inflammation (eicosanoid metabolites).
- Maintain cell and mitochondrial membrane integrity—key to cell survival.
- Foundational to the core physiological clinical imbalances (see ◘ Fig. 11.1).
- Provide structural integrity



◘ **Fig. 11.2** Fluid mosaic model of membrane structure. (Reprinted from OpenStax CNX [88]. With permission from Creative Commons License 4.0: ► https://creativecommons.org/licenses/by/4.0/)

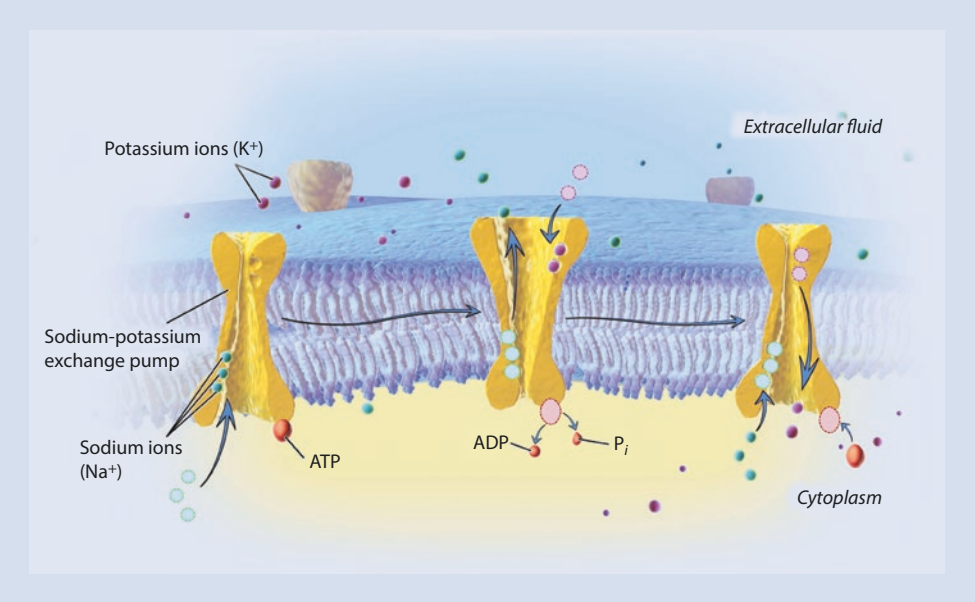


Fig. 11.3 Sodium-Potassium Pump. A transporter on the membrane that maintains high potassium and low sodium intracellular concentrations relative to the extracellular electrolyte concentrations. This pump functions at the expense of ATP energy and is influenced by the dietary intake of the minerals magnesium, potassium, and sodium. (Reprinted from ► Blausen.com staff [89]. With permission from Creative Commons License 3.0: ► https://creativecommons.org/licenses/by/3.0/deed.en.)

- Provide defense and repair.
- When compromised or damaged, allow healthy molecules to leave the cell and unwanted materials to enter. This can be referred to as "leaky cell membranes.
- Phospholipids, fatty acids, cholesterol, and proteins when in balance facilitate repair and maintenance of cell membranes.
- Sodium-potassium pump (see Fig. 11.3).
- Intracellular cytosol 97% potassium controlled by the sodium-potassium pump (Fig. 11.3).

11.4.1.1 Cellular Hydration

Among the many properties of the cells and organelles is hydration. Measurable aspects of cell hydration include total body water, intracellular water, and extracellular water [2]. These measurements are clinically available using bioelectric impedance analysis (BIA) (see ► Chap. 22). All metabolic characteristics apply to the balance of water between intracellular and extracellular fluids [2, 9]. In healthy cells, there is opposite composition of the intracellular potassium concentration versus the extracellular sodium managed by the sodium-potassium pump (Na-K pump) embedded in the cell membrane [9]. ATP production is the energy driving the activity of the pump [2, 10].

- Intracellular matrix (cytosol) is 97% potassium-controlled by the Na-K pump [9]
- Extracellular matrix is 97% sodium-controlled by the Na-K pump [9]
- Magnesium rate-limiting nutrient for the Na-K pump [10]

A deficit of any of the three minerals will affect the function of the Na-K Pump and cellular hydration.

11.4.1.2 The Membrane Barriers: Organelle, Cell, Tissue, and Organs

All membrane barriers contain the basic bimolecular bilayer membrane structure. That basic structure is found in every type of cell, organelle, tissue, or organ function, with only slight variation. Examples are that neuron cells have a higher percentage of phospholipids than liver cells and heart and muscle cells have a greater percentage than brown fat cells (see ► Chap. 12).

The most important barriers to be considered when assessing body systems are:

- Skin (see ► Chap. 54)
- Gastrointestinal barrier, with small intestine housing about 70% of immune cells in the lymphoid tissues (see ► Chap. 24)
- Blood–brain barrier (see ► Chap. 12)
- Respiratory-lung barrier, comprised of bronchi, bronchioles, and alveoli cells which together are responsible for exchanging oxygen intake and carbon dioxide waste exhalation (see ► Chap. 52)

Significant differences in the membrane structures of various cells, besides phospholipid composition, are in the presence and amount of cholesterol. Mitochondria have almost no cholesterol embedded in their inner and outer membranes. In all other eukaryotic cells (complex cells with organelles), cholesterol is present and is important to the stability of the cell, the sorting of protein structures [2], and guarding from toxic substances entering the cell.

During the twentieth century, cholesterol developed a bad reputation driven by the Ancel Keys' research concerning its relationship to cardiovascular disease. More recently, the scientific community has challenged Keys' research on cholesterol and saturated fat [4].

It is important to consider the beneficial role of cholesterol in the structure of the membrane. Cholesterol is a "lipid of its own" [2]. Cholesterol is a sterol and is different from phospholipids. Cholesterol has a steroid ring structure and polar head group (-OH). As an amphipathic molecule possessing both lipophilic and hydrophilic properties, cholesterol easily incorporates into lipid bilayers. Cholesterol has a "bulky and stiff tail and small head," contributing a stabilizing order to the cell membrane structure, making the membranes "stiffer" but allowing the membrane permeability to function. Membrane permeability is an important issue of chronic diseases and that the membrane signaling, therefore cell metabolism and viability, depends on the phospholipid, cholesterol, and fatty acid composition [1, 12]. The permeability of the organelle and cell membranes requires a balance that is not too rigid and not excess (leaky membrane). Membrane permeability is affected by several factors like age, dietary history, activity level, and hydration. A practical assessment of cell membrane permeability is the measurement of the *phase angle* (PA), a quantitative measurement available using the bioelectric impedance analysis (BIA) technology (see ▶ Chap. 22). The PA is used as a marker of cell membrane integrity and permeability. Although the biological significance of the PA is not fully understood, many studies have recognized that low PA values are associated with a poor prognosis and as a prognostic indicator for some cancers [11, 13, 14]. The BIA instruments have been used in research and clinical practice for over 30 years and are easy to operate in a clinical setting and relatively inexpensive. This BIA data when added to the information from a red blood cell (RBC) fatty acid analysis, blood lipid panel, and disease condition gives some indication of cell membrane permeability.

Cholesterol is essential to life by providing the base unit for production of hormones, neurological cells (neurons, myelin, brain tissue, etc.), bile, and others. As with all natural components of the chemical body, each cholesterol molecule has multiple functions. Each function depends on the balance of the amount of cholesterol deposited in the cell membranes. This balance is foundational to optimized cell function and may be related to compromised metabolism when cholesterol is too low (studies suggest hypocholesterolemia is total cholesterol <120–150 mg/dL). On the low-end of the spectrum, hypocholesterolemia is associated with increased incidence of mood disorders like depression, as well as cancer, and sepsis [15]. During a nutritional assessment, biomarkers for cholesterol status are important to quantify and should consider any medications that influence cholesterol synthesis. The IFMNT practitioner should be skilled at restoring cholesterol balance and managing hypercholesterolemia along with helping manage clinical symptoms.

11.5 The Eicosanoid Cascade: Acute and Chronic Tissue Inflammation Management

The eicosanoid cascade is comprised of a complex group of organic molecules with multiple metabolic functions. This section will focus on eicosanoid functions and their influence on the immune response to initiate and resolve inflammation [1, 16]. The 20-carbon eicosanoids are derived from the 18-carbon fatty acids omega-6 linolenic acid (LA) and omega-3 alpha-linolenic acid (ALA) by catalytic action of two enzyme groups, desaturases and elongases. The dietary amounts of omega-6 and omega-3 fatty acids affect this process of eicosanoid production. The eicosanoid metabolites are signaling molecules that determine the function of many metabolic pathways. The families of eicosanoids include prostaglandins, prostacyclins, thromboxanes, and leukotrienes [10]. Within each family, there are many metabolites, including recently discovered *specialized pro-resolving mediators* (SPM), involved in resolving inflammation [1, 6, 17]. Eicosanoid families may either produce or reduce inflammation depending on which molecules are produced by the immune response signaling. Eicosanoids also help regulate blood pressure, modulate the immune system, and affect blood clotting [7].

The IFMNT practitioner applies their knowledge of the eicosanoid cascade biochemistry and rate-limiting nutrient cofactors and lifestyle habits that affect elongation and desaturase enzyme functions. With skill in managing chronic inflammation, one can target nutritional interventions to restore optimum balance of the eicosanoid metabolites derived from the essential fatty acids, *linoleic acid* (LA C18:2 ω 6), and *alpha-linolenic acid* (ALA C18:3 ω3) (see ◘ Fig. 11.4). To assess an individual's eicosanoid and metabolite status, obtain functional lab testing and a diet history to assess the patient's fatty acid status and metabolites affecting inflammation. The initial assessment best includes an RBC fatty acid profile, blood lipid panel, and dietary history of fat and oil rich foods (see ▶ Chap. 58 on Fats and Oils Survey). From this data, one can assess fatty acid status and recommend changes to support inflammation control.

The two arms of the eicosanoid cascade share the desaturase and elongation enzymes and compete for their use, with preference toward omega-3 metabolites [18]. Each of the omega-3 and omega-6 metabolite families influence each other and cannot be converted from one family to the other due to lack of the required enzymes in the human metabolism. Even though the LA and ALA are the two essential fatty acids, their important metabolites like γ-linolenic acid (GLA), di-homo-γ-linolenic acid (DGLA), arachidonic acid (AA) in the omega-6 family, and EPA and DHA in the omega-3 family can be obtained from some foods rich in the converted forms. For example, for a person who did not eat

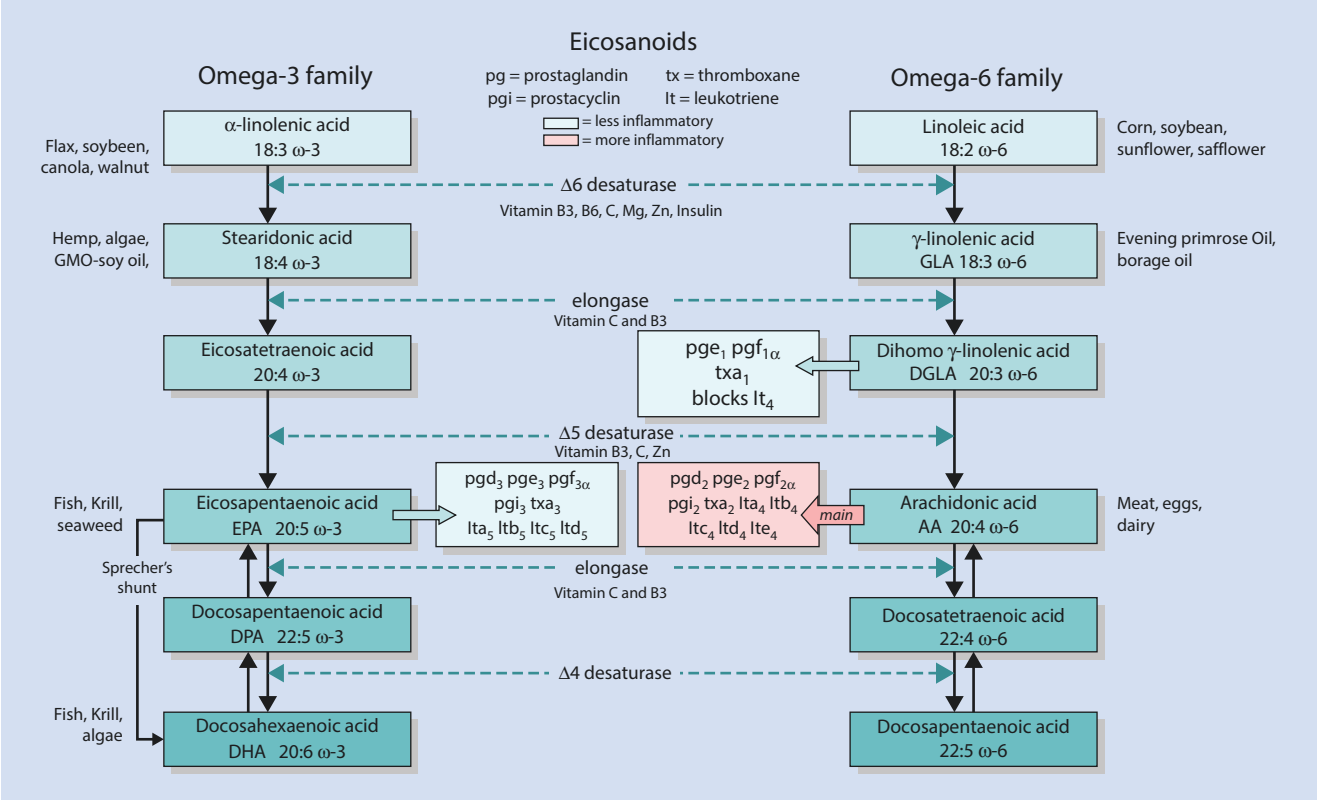

Fig. 11.4 The Eicosanoid Cascade of essential fatty acids, their metabolites, the nutrient cofactors, and foods rich in those cofactors. (Adapted with permission from: ► https://commons.wikimedia.org/wiki/File:EFA_to_Eicosanoids.svg)

any ALA sources like walnuts, flax oil, or vegetables, adequate EPA, and DHA could be provided by eating fish (EPA, DHA) or algae (DHA) sources. Another direct source of EPA, DHA, and LA is grass-fed or pasture-fed beef. If a person is depleted in the nutrient cofactors for the elongation and desaturase conversion biochemical steps, it would limit the efficiency of those enzymes. Repletion of those nutrient co-factors can increase the efficiency of the conversion enzymes.

11.5.1 Fatty Acid Elongation (See Fig. 11.4)

Elongation chemistry is dependent on the rate-limiting nutrients vitamin C and vitamin B3 (niacin). Any insufficiency or deficiency of those nutrients can significantly hamper achieving the balance of the eicosanoid metabolites. This balance is foundational to optimized cell function [19].

11.5.1.1 Elongase

The elongation of long chain fatty acids is derived from the omega-3 and omega-6 essential fats into very long chain fatty acids (VLCFA). The rate-limiting nutrient cofactors are zinc, magnesium, and vitamin B6. The elongation of very long (ELOVL) fatty acid by elongase enzymes is influenced by insulin and high carbohydrate diets [10]. It is important to assess glucose-insulin management when assessing of lipid status.

11.5.2 Fatty Acid Desaturation (See Fig. 11.4)

Desaturase enzymes delta-6-desaturase (D6D) and delta-5-desaturase (D5D) control the conversion of the essential fatty acids LA and ALA and eicosanoid metabolites. The key nutrient cofactors for the D6D and D5D are vitamins B3 (niacin), B6 (pyridoxyl-5-phosphate), C (ascorbate), and the minerals magnesium and zinc.

11.5.2.1 Delta-6-desaturase (D6D)

Interactions between dietary LA, D6D, and insulin resistance from the modern Western diet are associated with increased activity of the D6D enzymes, which result in the increased conversion of LA to excess pro-inflammatory AA [20, 21]. Alcohol and smoking can both suppress D6D activity, and those individuals may have poor conversion of LA to DGLA and AA. The GLA conversion to DGLA is a pivotal occurrence because the DGLA has two options for continued production of either the prostaglandin 1 series of metabolites or AA and the proinflammatory prostaglandin 2 series. The D6D and D5D enzymes determine how much the omega-6 metabolites proceed in either direction. If D6D is inhibited, not as much DGLA is produced. If DGLA is produced and D5D is increased in activity, DGLA will increase production of AA and lessen the ability to form the anti-inflammatory PG1 metabolites. For those who smoke and/or drink significant alcohol, the use of evening primrose or other GLA-rich

oil can support increasing DGLA conversion toward anti-inflammatory prostaglandin 1 metabolites and bypass the poor activity of D6D [6]. The D6D is encoded by the fatty acid desaturase (FADS2) gene and its function is rate-limiting in polyunsaturated fatty acid biosynthesis [22].

11.5.2.2 Delta 5-desaturase (D5D)

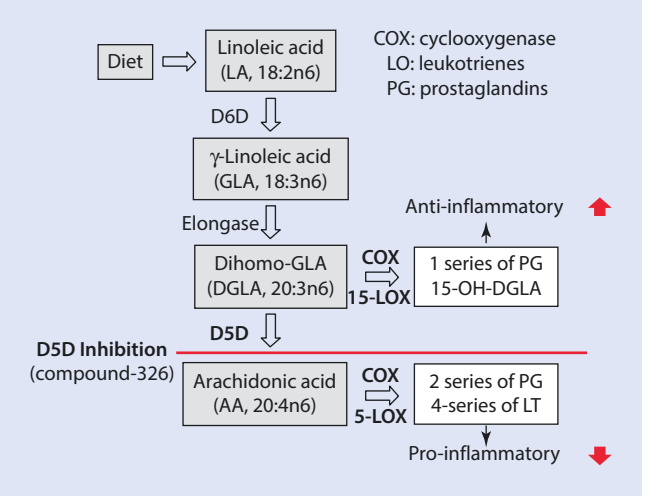
D5D activity is responsible for the conversion of omega-6 DGLA to pro-inflammatory excess AA. Elevated glucose, insulin metabolism, and obesity promote D5D activity, increasing AA formation and pro-inflammatory conditions. Dyslipidemia and the use of prescription medications (statins) are usually involved with increased D5D activity [3, 23]. Because of the epidemic of sarcopenic obesity and obesity overall, awareness of interventions such as supplemental GLA-rich sources can direct the omega-6 DGLA to its alternative anti-inflammatory pathway to prostaglandin 1 series metabolites and contribute to decreasing insulin resistance [23]. D5D is also involved in gonadal hormone metabolism. An example is when estrogen-dominant conditions develop, the D5D is more activated. This may increase conversion of DGLA to AA instead of a balanced conversion to the PGE1 anti-inflammatory molecules. Weight reduction to ideal body weight and weight maintenance can improve the healthy function of D5D [24].

It is important to remember that the omega-6 and omega-3 fatty acids cascades compete for the desaturase and elongase enzyme activities, so inhibiting the omega-6 DGLA to AA conversion will also affect the D5D activity that converts omega-3 ALA to EPA and then DHA. When inhibiting D5D, there may be an increased need for dietary intake of EPA and DHA by eating fish and/or fish oil supplementation. D5D enzyme activity is a target of research for diabetes management. D5D inhibitors are currently a target of the pharmaceutical industry [24]. The potential of nutrition therapy to optimize fatty acid status, reduce simple carbohydrate intake, and achieve weight management can be powerful modulators of these enzymes.

More comprehensive lipid blood tests have recently become clinically available that can improve assessment of a patient's status. The arachidonic/di-homo-gamma-linolenic acid ratio (AA/DGLA ratio) is a meaningful biomarker for assessing balance between AA and DGLA concentrations that affect the inflammation process and the function of D5D [25] (See ◘ Fig. 11.5).

11.6 Metabolic Stressors

Systems biology emphasizes the interactions of all systems to influence the phenotype of an organism. New stressors have arisen in the past century from environmental toxicants, decreased physical activity, highly refined foods, increased carbohydrate intake, and increased occurrence of metabolic syndrome to enable dramatic changes in phenotype due to chronic disease. Some of these stressors are known to influence the activity of the elongases and delta-5 and delta-6-desaturases, resulting in altered eicosanoid metabolism. Obesity is one metabolic condition that is associated with disturbed lipid metabolism and low-grade inflammation in tissues, and can vary based on the nutrigenomic profile of an individual for the FADS1 and FADS2 genes (See ▶ Chap. 17).



◘ **Fig. 11.5** Biosynthesis pathway of n-6 polyunsaturated fatty acids. D5D is a key enzyme affected by glucose, insulin, and stress status of metabolism and can be mediated by diet and lifestyle choices. (Reprinted from Yashiro et al. [24]. With permission from Creative Commons License 4.0: ▶ https://creativecommons.org/licenses/by/4.0/)

> The functional role of eicosanoids in the inflammatory etiology of diseases of metabolic syndrome (MetS) has been extensively studied in relation to immune cell recruitment and cytokine, chemokine production and their activation of inflammatory pathways in cancer, diabetes, and cardiovascular disease (CVD) [11, 26].

11.7 Tools of the Trade for Lipid Therapy

The toolbox for the IFMNT practitioner considering lipid therapy assessments and interventions includes all clinical and measureable parameters and modalities that influence lipid metabolism or are influenced by food intake, lifestyle, and/or environment. The following checklists and principles of gathering lipid data suggest laboratory testing and other clinical information to contribute to a comprehensive assessment, diagnosis, and intervention to promote the best outcome for an individual.

Toolbox to identify fatty acid/nutrition status

- Nutrition Physical Exam (see ▶ Chap. 40)
- Medical history: diagnoses, medical event history, residential location
- Signs and symptoms: Medical Symptoms Questionnaire (MSQ)
- Laboratory testing: basic nutrition, lipids, disease-specific and sometimes patient-specific markers
- Bioelectrical Impedance Analysis (BIA), if available

The nutrients in ◘ Table 11.2 are the most studied regarding lipid metabolism and should be considered as part of a nutritional assessment.

Table 11.2 Key lipid nutrient insufficiencies/deficiencies associated with subclinical or acute disease; key immune nutrients foundational for healthy lipid status

Nutrient	Clinical or biochemical implication of deficiency	Reference	Symptoms	Testing to consider
Immune modulators				
Omega-6 GLA	Eczema, Dermatitis GERD Viral infections	[6]	Broken skin lesions Rash, diabetes Long-term effects of chronic disease	RBC fatty acid Gamma linolenic (GLA) di-homo-gamma linolenic acid
Eicosapentaenoic acid (EPA, EPA, DHA, LA, ALA)	Altered mood Skin health Cardiovascular Cancer	[27]		RBC fatty acid
Malonaldehyde	Cancer Altered fatty acid Metabolism	[6]		RBC fatty acid
Choline phosphatidylcholine phosphatidylethanolamine phosphatidylinositol	Poor membrane permeability Impaired fat metabolism Fatty liver Mitochondrial dysfunction Released alanine aminotransferase (ALT) from liver cells	[28, 29]	Neurological Fat malabsorption Muscle damage	Homocysteine Creatine kinase Liver enzyme ALT Lipid panel Folate, RBC folate
Vitamin D	Immune modulator	[30–32]	Mood disorders Bone loss Joint pain Compromised immunity	Vitamin D25OH Vitamin D 1,25OH Parathyroid hormone (PTH) Ionized calcium
Vitamin A retinol	Mucosal immunity	[33, 34]	Mucosal bacterial/viral infections	Vitamin A, retinol B-carotene
Eicosanoids	Anti-inflammatory Pro-inflammatory Immune regulation Resolution biology	[35–37]	Pain Swelling Cancer	RBC fatty acid
Rate-limiting co-factors				
Folate	NK cell activity Cytotoxic cellular immunity Modulate T-cell responses	[38]	Fatigue Infection Mood disorder	Folate, serum RBC folate FIGLU
Zinc	Regulates intracellular signaling pathways in innate and adaptive immune cells	[38–40]	Skin conditions Poor smell Poor taste Frequent illness Nail spots	Zinc, serum RBC zinc
Magnesium	>300 enzymes cofactor Urine excretion under stress Muscle tension Camps	[10]	NHANES ~80% US population less than RDA magnesium	Magnesium, serum RBC magnesium
Antioxidants				
Vitamin C	Regulates cellular humoral immune function Increases macrophage Antihistamine Requirements increase during infection Anti-viral	[41]	Connective tissue impairment Skin conditions Poor wound healing	Vitamin C, blood CPT 82180 Urine, functional need for vitamin C test: urine *p-hydroxyphenyllactate* (HPLA)

(continued)

Table 11.2 (continued)

Nutrient	Clinical or biochemical implication of deficiency	Reference	Symptoms	Testing to consider
Vitamin E	4 tocopherols + 4 tocotrienols protective from oxidative stress/ lipid peroxides	[30, 42]	Oxidative stress Premature wrinkles Cysts Leg cramps	Serum: Alpha-tocopherol gamma-tocopherol
Selenium	Thyroid peroxidase metabolism with vitamin E Selenoproteins special effects on cellular immunity Resistance to viral infections Central to glutathione peroxidase structure	[38]	Hypothyroid Low glutathione blood levels Impaired detoxification	Selenium, serum RBC selenium
GUT secretions				
Short-chain fatty acids (SCFA)	Intestinal cells Anti-inflammatory Microbiome-gut- brain axis via immune system/vagal nerve Mucosal immunity	[43–48]	Inflammation Perturbed uric acid cycle Colon disease	Acetate Propionate (blood or fecal) Butyrate (blood or fecal)
Bile acids	Fat malabsorption Metabolic liver diseases Glyco and Taurochenodeoxycholic Acid	[49, 50]	Perturbed fat digestion	Bile acids US imaging gallbladder
Lipotoxic Conditions				
Dysfunctional regulation of lipid metabolism and homeostasis causes cellular lipotoxicity, impairs cellular processes and contributes to the pathogenesis of disorders such as obesity, atherosclerosis, and neurodegeneration	Neurological Cancer Autoimmune Developmental Cardiovascular Psychological	[51, 52]	Diagnosis specific	Diagnosis specific
Anti-Nutrients				
Endocrine-disruptors	Circadian rhythm disruption that can modulate immune function	[53, 54]	Hormonal imbalance Insomnia Cancer	GPL-TOX, Great Plains Lab toxic organic chemical profile
Damaged food components/ Western Diet & food preparation Trans fat Oxidized fat Toxic metals Toxic chemicals "new to nature molecules" (cookware, pest control, pollutants, processed, etc.)	Most damaged or toxic substance *Lipophilic* and embed into the fatty membrane and other tissues Damaged high-heat foods Chemicals Toxic metals ingested in foods and from food utensils during food preparation	[55]	Chronic disease Specific toxic symptoms Weakened immune integrity	Diet History RBC fatty acid analysis
Environmental Toxins				
Mold/mycotoxins Natural gas carcinogenic Chemical vapors Pesticides	Neuropsychiatric Immune disruption Vulnerable to poor cell signaling Insulin resistance	[56, 57] [58] [59]	Toxicities Chronic kidney failure Infertility Cancer Developmental Frequent infections	*Mold, pathogenic bacteria:* Multiple Antibiotic Resistant Coagulase Negative Staphylococcus (MARCoNS) nasal swab GPL-TOX, Great Plains Lab toxic organic chemical profile (pesticides, toxic chemicals)

11.7.1 Laboratory Principles

With laboratory data available, a diagnostic profile can clarify the priorities of core physiological imbalances and provide clues regarding nutrition and lifestyle therapy to restore structure and dynamic function of the membrane. From the IFMNT nutrition assessment, consideration of the two most likely physiological clinical imbalances is *structural integrity* and *defense & repair* (see ◘ Fig. 11.3).

11.7.2 Structural Integrity

The membrane's structural integrity affects the transport and communication of the cell membrane and receptors. If there is a history of head, neck, dentition, or back injury where there may be a possible structural misalignment in the cervical vertebrae, the brainstem and vagal nerve may be impaired. Someone with this history should be referred to a cranial specialist for evaluation and have their lipid status reviewed.

11.7.2.1 Assessment Checklist for Structural Integrity

- Cell membrane permeability and integrity (BIA phase angle, fatty acid status) [11]
- Dental periodontitis: infection of the tissues that surround the teeth-inflammation
- Structural-spinal alignment: neuronal membrane [1, 60]
  - Cervical C1-C7 – brainstem & vagal assessment – check vagal tone
  - Thoracic T1-T5 – stenosis or injury increased pain resulting in exaggerated immune inflammatory response
  - Lumbar L1-L5 – stenosis or injury increased pain resulting in exaggerated immune inflammatory response

11.7.3 Defense and Repair

Defense and repair are managed by a dynamic immune system that responds to endogenous and exogenous infection, injury, malnutrition, altered gut microbiome, stress, and other potential inflammatory triggers.

11.7.3.1 Assessment Checklist for Defense and Repair

Blood Markers

Vitamin D 25-Hydroxy

Vitamin D has many functions. It is a powerful immune modulator that plays a role in defense and repair.

> Vitamin 25OH serum levels have been associated with overseeing the dynamics of the cell membrane. Vitamin D seems to stimulate anti-inflammatory processes [31].

Vitamin A (Retinol) [61]

Vitamin A is a nutrient cofactor for the eicosanoid desaturase enzymes. It is increasingly recognized in experimental and human studies to enable suppression of inflammatory reactions and plays a significant role in normal mucosal immunity, regulation of T cell-dependent responses, antiviral activity, and cell communication.

Adequate vitamin A status, whether from intake of preformed retinol (e.g., animal sources: egg yolk, organ meats, fish, shellfish, and roe) or from b-carotene (e.g., yellow and green vegetables) is important for preventing excessive or prolonged inflammatory reactions and supporting the eicosanoid cascade [61].

Gut microbiome [55]

Gut commensal bacteria making up the microbiota are critical for the health of the immune system by defending and repairing the intestinal barrier where >70% of the immune cells reside. Stool testing provides biomarkers to assess GI ecology. From this data one can develop an intervention plan to correct and repair imbalances in the gut microbiome (see ▶ Chap. 24).

Inflammatory Load Assessment

- High-sensitivity C-reactive protein (hs-CRP): acute-phase-reactant and marker of systemic inflammation. It is often elevated due to bacterial infection, central adiposity, fatty liver, neoplastic activity, or traumatic injury. All clinical laboratory references include normal hs-CRP as ≤1.0. Its elevation implies potential bacterial infection or physical trauma. If no dental/oral infection is identified, begin further investigation of the root cause. It is important to rule out a recent traumatic injury that may be related, and hs-CRP should be retested in a month or two to observe if injury has affected the hs-CRP.
- CBC with differential
- Complete metabolic panel (CMP)
- Lipid panel
- Erythrocyte sedimentation rate (sed rate)
- TSH
- Bacterial/viral evaluation if indicated; saliva or blood
- Genomic testing (saliva), if available

11.8 Key Nutrient Cofactors and Foods Influencing the Eicosanoid Metabolism

11.8.1 Lipids

Lipids play critical roles in membrane structure, cell signaling, energy storage, control of inflammation, and as base units for constructing messenger hormones [2]. Each member of the family of lipids has specialized functions. Some provide cell signaling, cellular component transporting and regulate immune response of inflammation, hormonal modulation, and other undiscovered functions. When there is

poor structure, dysfunction occurs [62]. The following key nutrients below can be obtained from foods and/or dietary supplements:

11.8.1.1 Phospholipids (PL)

Phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylserine (PS). These phospholipids are ubiquitous in all membrane structures and especially important for the functions of neurological and mitochondrial membranes [6]. The body can synthesize them, and they can also be found in foods. Foods rich in phospholipids are animal meats and organs, egg yolk, and legumes.

11.8.1.2 Fatty Acids:

- *Omega 9* Monounsaturated fatty acids (MUFAs): These oils are stabilizing components of structures and also have an anti-inflammatory effect in metabolism. Foods rich in MUFAs are olive oil, avocado/avocado oil, almonds, sesame, and peanuts. They are mildly heat sensitive and best raw or used with low heat.
- *Omega 6* Linoleic Acid (LA) (essential) and the eicosanoid metabolites GLA, DGLA and AA. LA is rich in seeds, some nuts, greens, grains and grasses.
- *Omega 3* Alpha Linolenic Acid (ALA) (essential) and the eicosanoid metabolites EPA, DPA, DHA recognized for their anti-inflammatory effects on metabolism. The balance between omega 6 and omega 3 fatty acids is important with most fatty acid scientists proposing an optimum ω6:ω3 ratio range of 1:1 to 5:1.
- *Saturated fatty acids* have been blamed as being detrimental for humans. But better understanding that there are beneficial saturated fatty acids when maintained at about 10% of dietary fat [63]. Natural and beneficial forms of the saturated fats are:
  - *Short chain fatty acids* (SCFA) with many critical roles of anti-inflammatory and fuel for colonocytes. Many health benefits are recognized reducing risk of colon cancer, autoimmunity, and gastrointestinal disease.
    1. Acetate (C2) and Proprionate (C3) SCFAs are formed in a healthy gut.
    2. Butyric Acid: butyrate: C4: butyrate-rich sources are butter, mother's milk, healthy gut microbiome consuming resistant and soluble vegetable and fruit fibers to produce SCFAs, and sodium or calcium-magnesium butyrate dietary supplements. If there are infectious or antibiotic insults to the gut microbiome, the production of butyrate may be notably reduced [64].
  - *Medium chain triglycerides* (MCTs) are composed of a glycerol backbone with three medium-chain fatty acids (MCFAs) (C6-C12). The MCTs are beneficial as part of dietary intake. They are heat resistant and recommended as cooking oil. Rich sources are coconut oil, palm kernel oil, and ruminant animal milk (cow, sheep, goat, horse). Therapeutic use of MCTs for liver failure and other gastrointestinal conditions is common due to their rapid absorption and not requiring bile salts for digestion and can be an easily metabolized source of energy.
  - *Saturated Fatty Acids (SFAs)*(C13-16) are made up of carbon chains with only single bonds. The body can synthesize SFAs and they are also found in SFA-rich foods such as animal meat fats like beef tallow, pork lard, poultry fat, and also cocoa butter.
  - *"New-to-nature" Fats:* with high heat and hydrogenation processing of vegetable oils, aberrant fatty acids and lipid structures can be formed that have been recognized as unhealthy for human metabolism, with some identified as carcinogenic. Examples of these compounds are trans fats and acrylamides.

11.8.2 Sterols

Sterols are naturally occurring unsaturated steroid alcohols, waxy lipids. The primary sterol for human metabolism is cholesterol, which is the base unit for all hormone production and vitamin D. Cholesterol is also an important component of cell membrane structure [2]. Most endogenous cholesterol is synthesized by the liver, but dietary cholesterol can influence total cholesterol levels. Foods rich in cholesterol are of animal origin: fats from animal milk, meat, egg yolk, poultry, seafood, and organ meats.

11.8.3 Minerals

11.8.3.1 Zinc

Zinc is a nutrient cofactor for the desaturase and elongase enzymes and a nutrient partner with copper. Zinc and copper should always be balanced in body fluids (see ▶ Chap. 8). When copper is elevated, it promotes increased fat deposition in some organs like the liver. Increased zinc intake can modulate the copper to a healthy level and reduce the fat deposition [65].

11.8.3.2 Magnesium

Magnesium functions as a nutrient cofactor for both the desaturase and elongase enzymes for eicosanoid conversions. When it is insufficient or deficient, restrictions in function can occur. In the case of magnesium as a cofactor in the sodium-potassium pump, the rate of conversion is decreased during a deficiency of magnesium. Magnesium is the cofactor catalyzing the enzymes driving the sodium-potassium pump, moving substances in and out of the cell through the lipid membrane [9, 66, 67] (see ▶ Chap. 17).

11.8.4 Methyl Nutrients

Vitamins B6, B12 (-cobalamins), B9 (Folate), B2 (riboflavin), B3 (niacin), choline (betaine, phosphatidylcholine/phosphatidylethanolamine), SAMe, and related Vitamin C, B1, B5 [68, 69].

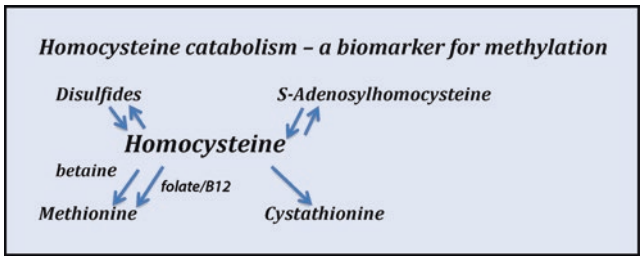


Fig. 11.6 Homocysteine major metabolic pathways in humans. (Adapted from Dudman et al. [70]. With permission from Oxford University Press)

Methyl nutrients support the process of methylation, having many roles within human metabolism with DNA methylation being the underlying mechanism, and they currently appear to be primary messengers of epigenetic expression (see ▶ Chap. 18) identified in the etiology of developing cardiovascular, cancer, and neurological disease conditions. Methyl nutrients are involved in the conversion of desaturase and elongase enzymes. Methylation involves biochemical pathways where the B vitamins and other cofactors like amino acids are rate-limiting cofactors [70] (Fig. 11.6).

11.8.4.1 B12 and Folate Metabolism

B12 in the natural bioactive forms (methyl-, hydroxy-, or adenosylcobalamin) is a nutrient cofactor that inhibits the excessive formation of arachidonic acid. B vitamins team together, and folate is an especially important teammate with B12. Folate is critical to many metabolic pathways like nucleic acid precursors, several amino acids, and erythropoiesis, which is the process in which new erythrocytes are produced. A biomarker that can suggest folate deficiency is an elevated mean corpuscular volume (MCV) on a complete blood count quantitatively measuring size of RBCs. Folate deficiency can be part of the etiology of enlarged RBC or megaloblastic anemia, from ineffective erythropoiesis. Additionally, Vitamins B6 and B12 are cofactors involved in erythropoiesis [71].

11.8.4.2 Niacin, Vitamin A, Vitamin C, and Zinc

- Rate-limiting nutrients for DGLA conversion to anti-inflammatory Prostaglandin 1 (PG1) series
- PG1 anti-inflammatory action primarily involved in mediating conditions of allergy, viral, autoimmune

11.8.4.3 Vitamin D, A [72]

These fat-soluble vitamins have many metabolic roles. Their influence on structural integrity and defense and repair (e.g., inflammation and immune response) modulates the lipid environment and metabolic dynamics. The fat-soluble vitamins function synergistically, with the vitamin D and A receptors sharing their nuclear receptor, influencing each other. Vitamin D2/3 and A are found in their food-rich sources together (e.g., liver, caviar, /roe, egg yolk). Vitamin A retinol is one of the key nutrient cofactors for the desaturase enzyme activity.

11.8.5 Phytonutrients: Protective Support for Lipid Structures

- Inflammation: Phytonutrients are antioxidants that protect the lipid membrane from oxidative stress through their powerful polyphenols found in a variety of pigment-rich fruits, vegetables, grains, nuts, teas, herbal spices, and legumes that have anti-inflammatory properties. The mechanisms of the plant chemicals include antioxidants, antibacterial, and antiviral. Even though phytonutrients are not considered essential nutrients, the evidence is mounting for their critical role in health maintenance and anti-aging.
- Biomarkers of poor phytonutrient status: Poor dietary intake of high polyphenol foods. Significant biomarkers for inflammation can be related to poor vegetable and fruit intake and lack of (or imbalance in) dietary intake of healthy fats and oils (see ▶ Chap. 58 Fats & Oils Survey)(Table 11.2)
- Resource: The Rainbow Diet. Color Can Heal Your Life [73].

11.9 Key Lifestyle Factors Influencing the Risk of Lipid Damage

11.9.1 Sleep [74] (See ▶ Chap. 35)

Sleep and circadian rhythm have a great influence on the integrity of the immune system. Much evidence has accumulated over the past decades associating poor sleep quantity and quality with weakening of the immune system, increasing vulnerability to the poor function of cellular structures.

11.9.2 Stress (See ▶ Chap. 47)

Chronic stress impacts every biological and psychological system. When the chemical microenvironment is under long-term stress, it pushes the immune system response into chronic inflammation and increased acidity. The vicious cycle continues until the threshold of resilience and adaptation is exceeded, leading to vulnerability to many chronic diseases including damage to lipid structures and influencing the eicosanoid metabolism.

11.9.3 Movement (See ▶ Chaps. 36 and 54)

As with all biological systems, there must be movement of structures like muscles, heart, lungs (breathing), as well as the fluids in the body to maintain health. Without movement, there is congestion that does not support healthy metabolism. The health of the immune system is dependent on the lymphatic system, which is supported by movement. The lymphatic circulatory system does not have a pump as compared with cardiovascular circulation. The lymphatic vessels are "pumped" by physical activity with arm and leg movement, abdominal breathing, laughing, etc.

11.10 Chronic Disease and Impaired Lipid Metabolism (See Tables 11.3 and 11.4)

11.10.1 Heart Disease/Cardiovascular Association with the Lipidome

Lipids manage and resolve inflammation via the eicosanoid cascade. Chronic inflammation is a hallmark of cardiovascular disease, so if it is well controlled and resolved, the risk of a cardiovascular event is decreased. The current recommendation for eating fish or fish oil supplementation to benefit the cardiovascular system is primarily as a modulator of the eicosanoids to lower the pro-inflammatory excess omega 6 arachidonic acid [78].

11.10.2 Oncology

Several of the eicosanoid metabolites are evidenced to be tumor suppressive [79]. Eicosanoids, including prostaglandins and leukotrienes, are biologically active lipids that have been associated with many of the pathologies of chronic disease such as inflammatory cancer. Eicosanoid metabolites and their function of inflammation control give the IFMNT practitioner the ability to develop a targeted intervention for cancer by assessing the patient fatty acid status and analyzing the eicosanoid metabolism status [80].

Prostaglandins and leukotrienes can modulate tumor epithelial cell proliferation and apoptosis.

When the prostaglandin 1, 2, and 3 series are in balance, they can provide a change in the microenvironment toward wellness [81].

11.10.3 Neurological

11.10.3.1 Mitochondrial Dysfunction

Most neurological conditions involve underlying mitochondrial dysfunction. The mitochondrial inner and outer membranes are sensitive to influences from dietary fat. The inner membrane especially requires the phospholipid derived from choline, phosphatidylethanolamine (PE), and gamma-linolenic acid (GLA). Lipid nutrition therapy can use seed oils like evening primrose, black currant, sea buckthorn, or borage to provide adequate GLA in interventions to support mitochondrial repair. Evening primrose oil has also been shown to induce apoptosis and tumor suppression for cancer patients [82].

11.10.3.2 Alzheimer's Disease

The brain is approximately 70% fat and phospholipids. Restoring optimum lipid balance can benefit the structure and function of the nervous system. Comprehensive medical nutrition therapy supports high-fat diets in Alzheimer's and other neurological conditions. The brain can use glucose or ketones for fuel. Research on the ketogenic diet, where

Table 11.3 Laboratory: recommended biomarkers for lipid assessment

Blood tissue testing [75]
Lipid panel
Total cholesterol, HDL, LDL, triglycerides, lipoprotein particles [1]
RBC fatty acid analysis
Blood biopsy
Dietary fat intake reflected in RBC fatty acid membrane composition [76, 77]
Bioelectric impedance analysis (BIA) [11]
Phase angle: cell membrane permeability of the lipid bilayer
Capacitance: ionic potential, membrane surface biomarker
Intracellular and total body water
Organic acids [75]
Urine: first morning collection, fasting
View of all major systems (conventional and functional tests as indicated)
Inflammatory load
Clinical observation of any inflammation of the face, skin, pain, biomarkers?
Laboratory
CBC with differential
Sed rate
C-reactive protein-high sensitivity
Acute phase reactants per diagnosis or signs & symptoms
Nutrition physical exam: Barriers; rule out potential symptoms or history
Skin: tone, color, texture, lesions, skin tags, abnormal pigmentation
Lung capacity/O_2 Sat: optimum 98–100%; history lung disease or surgery
Gastrointestinal health: Comprehensive Digestive Stool Analysis (CDSA) abnormalities
Oral cavity: periodontal disease, swollen glands, tonsillectomy history
Esophagus: symptoms of esophageal pain/irritation, dysphagia, *Heliobacter pylori*
Stomach: pain, digestive upset, surgical history, vagal tone
Duodenum: structural changes, Small Intestinal Bacterial Overgrowth (SIBO)
Jejunum: structural changes
Ileum: structural changes, abnormal BM/bile circulation reentry
Colon: abnormal BM
Rectum: abnormal BM, hx colonoscopy
Pain: location, barrier involved
Fatigue
Time of day, meal timing, sleep quality and quantity, sleep apnea

Table 11.4 Lipid-supportive foods, herbs, and dietary supplements

Foods
Whole-foods, pesticide-free, vegetables and fruits in a variety of colors, adequate protein, healthy fats & oils, herbs, fluids; Minimize or avoid processed and high-sugar foods and beverages; avoidance of antigenic foods.
Oil-/fat-rich foods
Plant-based: avocado, raw seeds, olives, hearts of palm, nuts: macadamia, pine nuts, almonds, Brazil nuts, coconut oil
Animal source: organ meats, meat, poultry, fish, shellfish, roe, krill
Herbs
Turmeric/curcumin
Proteolytic enzymes: Bromelain, papain, trypsin, etc. (contraindicated for Alpha-1-Antitrypsin deficiency+ genetics)
Resveratrol
Boswellia
Diet
Macronutrient distribution
Insulin-glucose management
Meal timing
Intermittent fasting
Calorie restriction
Dietary supplements
Lipids
Phospholipids: phosphatidylcholine/phosphatidylethanolamine
GLA: evening primrose oil; black currant, sea buckthorn, and borage
Arachidonic acid: grass-fed meats, poultry, egg yolk.
EPA/DHA: various ratios are available; DHA vegan/algae; fish (ideally, lower on food chain)
ALA: cold nitrogen processed seed and nut oils flax oil and/or ALA-rich raw/soaked nuts, seeds, vegetables; sensitive to heat, light and oxygen.
LA: cold nitrogen processed seed and nut oils: refrigerated; sensitive to heat, light and oxygen.
Butyrate: short chain fatty acid (SCFA); sodium-potassium butyrate, calcium-magnesium butyrate, sodium butyrate, Rx: glycerol phenylbutyrate (Ravicti®), sodium phenylbutyrate (Buphenyl®)
MCT Oil: medium chain triglyceride; sources: coconut, palm and breast milk fats; MCT: Caproic acid (C6:0), caprylic acid (C8:0), capric acid (C10:0), lauric acid (C12:0)
Co-nutrients
Vitamin C (contraindicated for hemochromatosis mutation genetics)
Adequate methyl nutrients: B6, folate, B12, choline (betaine) and related B1, B2, B3, B5, Biotin, Vitamin D3, vitamin A (if indicated per personalized assessment)
Zinc: rate limiting nutrient to D5D, D6D, and elongase enzyme
Magnesium: rate limiting nutrient to D5D, D6D, and elongase enzymes
Personalize recommendations based on patient assessment

ketones are produced from high-fat low-carb diets, inducing a "nutritional ketosis", has shown therapeutic benefit in neurological conditions (see ▶ Chap. 23) [83–85].

11.10.3.3 Developmental Plasticity

Fetal and early childhood metabolic plasticity includes rapid growth of cells requiring lipids. The rapidly maturing brain and neurological system are high-fat cells that need lipids for membrane structure, cell signaling, and development of the immune system. Maternal health and nutrition status are important to secretion of fat-rich mother's milk, which lays the foundation for fetal growth [86].

11.10.4 Respiratory

The lung has a major protective barrier function in the body, and the lipid composition of the membrane is integral to modulating inflammation and promoting optimal function. Assessing and prioritizing the structural integrity and inflammation load using diet history, nutrition physical exam, and testing for nutritional status provide the foundation for developing a targeted intervention.

11.10.5 Autoimmune

Autoimmunity is the loss of immune recognition of self and non-self with resulting self-damage. Ongoing research has identified genetic relationships that have susceptibility to the development of autoimmune conditions (see ▶ Chap. 49). Chronic inflammation is present in all autoimmune conditions with resulting oxidative stress and reactive oxygen species that can damage lipid structures. Nutritional therapy considerations to reduce the chronic inflammation can be reducing or eliminating identified antigenic foods and replete nutrients that are insufficient or deficient.

11.11 Case Reviews

The following cases give examples of clinical application of lipid nutrition therapy. Each patient case presenting to an IFMNT practitioner needs to be approached as unique. Every diagnosis or symptom can have a multitude of root causes. The patient's story begins with an investigation to identify metabolic priorities and the focus of interventions using food, dietary supplements, and lifestyle to restore health. It is important to monitor interventions to assess effectiveness and determine if adjustments should be made.

Case Review: Simple Childhood Asthma

Diagnosis: Severe asthma
Male: age 8
Medical History:
- Asthma medications: Singular, albuterol inhaler, glucocorticoid inhaler- Budesonide and formoterol (Symbicort), salmeterol (Serevent). Fluticasone and salmeterol (Advair Diskus)
- Asthma emergency hospital ER event monthly

Laboratory Significant: CBC WBC 3.8, MCV 99 HI, Vitamin D 12 ng/mL; +grass and + casein IGE allergens

Nutrition Physical: depressed affect; depapillation pale tongue (low B6, B12, Folate, B2 and iron), corner lips cracked skin (low B2), pale skin, matty hair

Diet and Supplement history: Eighty percent fast food (hamburgers, hot dogs, cold cereal, cow milk casein, soda, yogurt, ice cream, toast, candy). No dietary supplementation.

Lifestyle: difficulty breathing, grass pollen allergy, no outside play (reduced sun exposure); poor sleep related to breathing difficulty.

Metabolic Priorities and Intervention Plan
- Remove antigen: cow's milk
- Remove empty calories: sugar, processed and refined foods, damaged oils
- Gut ecology: diet associated with poor gut pre and probiotics
- Get nutrients:
- EPA 350 mg/DHA 250 mg/GLA 130 mg supplement daily
- Vit D3 4000 IU emulsified D3 daily
- B Complex: bioactive forms – chewable
- Probiotic 450 billion powder in 6 oz. coconut yogurt daily
- Whole grain gluten-free bread for sandwiches, toast with organic butter
- Beverages: water, stevia-sweetened sodas, almond or coconut milk

Monitor: 6-Week Follow-up
- Happy affect, started 2 weeks able to take gym classes outside
- Nutrition: decreased probiotic; continued diet and remaining supplements

Follow-up plan: 3 Months
- Doctor removed four of the medications
- No hospitalization for asthma event

Outcome
- High school soccer team player, no asthma medications, continued casein-milk free diet and avoid high sugar foods, resumed gluten foods
- Annual physical: recommend Vitamin D25OH and maintain 40–60 ng/mL using vitamin D3 supplements and safe sun exposure.

Case Review – Early-Onset Alzheimer's

Patient Story: A 64-year-old male who presented with memory problems and diagnosis of early onset Alzheimer's disease by neurologist. Two months previous he showed no interest in activities, could not work. He was a building contractor for 35 years.

Medical History: Thyroid cancer, total thyroidectomy, and Hemachromatosis recessive.

Medical Data: Anthropometrics: BMI 30; height 76.2"; weight 250 lbs,

Dietary/Alimentation: High intake of soda (~2 quarts/day) and processed foods including gluten containing grains and starches; some candy, doughnuts, fried foods, fast food, and canned fruit; commercial lunch meats. Low intake of water, essential fatty acids, vegetables, and whole foods.

Nutrition Physical Exam: Memory deficits reported by wife and observed during exam, wrinkles beyond age appropriate (implies high oxidative stress), talks very slow and only when asked a question, poor dentition and dental hygiene, bleeding gums, very coated tongue with central crack.

Medications: Thyroid, Finasteride, Terazosin for prostate enlargement, and a baby aspirin daily.

Genotypic Risks: Family history of cancer (7 of 8 siblings and father); brother and uncle with Alzheimer's; son Hemachromatosis (BB polymorphisms).

Biochemical Lab: Mildly reduced GFR, high BUN, low TSH (0.03)/standard of care post thyroidectomy, PSA 1.19, high Homocysteine 18. Low albumin 3.9, Total Protein 6.3, Globulin 2.3.

Nutrition Assessment
- *Intake:* High sugar, processed foods and cured meats
- Digestion & Assimilation & Elimination: RZ reports a 1/week bowel movement
- *Utilization:* Cellular & Molecular Function:
- *Minerals:* Low magnesium, low-end blood electrolytes, BIA Capacitance 730 (goal ~ 1300)
- *Antioxidants:* Water Soluble: Vitamin C, Phytonutrients: severe skin wrinkles-poor Vit C, vegetable/fruit intake
- *Protein*: Low-end protein status; albumin 3.9
- Vitamin D & Fat soluble vitamins: Low vitamin D (25 ng/mL)
- *Oils/Fatty Acids:* Low omega-3 and omega-6:GLA intake foods; cholesterol panel is OK
- *Methylation*: elevated Homocysteine implying poor methylation; low folate, B12, MCV 101 HI, MCH 33

Plan: (Continued Early-Onset Alzheimer's)
1. *Elimination Diet*: Avoid sugars, soda-replace with tea or fresh lemonade; avoid cured meats, dairy, processed foods; eat more whole foods, sea salt, salads and no nitrate, eat high-quality meats; increase water intake to 2 qts/day (previous intake none). GOAL: reduce sugar intake and antigenic foods; increase phytonutrients, nutrient-dense-high-fiber food intake. Good family support.
2. Improve Methylation and Oils/Fatty Acids: Focused on neurological support;

Supplement with multivitamin, magnesium, EPA/DHA 1:1, GLA 370 mg QD, folate (5-MTHF 800 µg) QD, B12 (Methyl B12 1000 µg QD), D3 4000 IU QD; herbal laxative support until BM QD.

3. *Adjunctive Physician-Supported Nutrition Support Using IV Lipid Therapy:* [phosphatidylcholine (PC) × 2 months, Glutathione, phenylbutyrate, assessed methylation support] twice a week for 8 weeks then start oral protocol of PC, Glutathione and Butyrate, methylating nutrients (5-MTHF, B12) as needed)

Outcome: After implementation of herbal colon cleanse, magnesium and increased water intake, at 2 weeks bowel movements increased to 1/day; Memory improved ~70% within 4 weeks. Great family support. Client returned to work and driving at 6 months, showing significant improvement. Continue diet, oral supplements. Follow-up monthly for 14 months then every 6 months while continuing oral phospholipid, methyl nutrients and very low sugar nutrition program. Continues cognitive function as long as on supplements after 7 years. Blood homocysteine 9, MCV 92, MCV 30.5. Neurologist reversed Alzheimer diagnosis after 14 months.

Case Review: Complex Neurological Condition

Female AR, age 20
Weight 70 lb, 46 inches, BMI 15.7 Underweight
Diagnosis

- Cardiofaciocutaneous (CFC) syndrome (Q87.1 ICD10); Genes are: *BRAF* (~75%), *MAP 2K1* and *MAP 2K2* (~25%), and *KRAS* (<2%). [Congenital malformation syndromes predominantly associated with short stature]; 23andme.com nutrigenomics: homozygous MTHF +/+, heterozygous VDR –/+

The *cardiofaciocutaneous (CFC) syndrome* is a condition of sporadic occurrence, with patients showing multiple congenital anomalies and mental retardation. It is characterized by failure to thrive, relative macrocephaly, a distinctive face with prominent forehead, bitemporal constriction, absence of eyebrows, hypertelorism, downward-slanting palpebral fissures often with epicanthic folds, depressed nasal root and a bulbous tip of the nose. The cutaneous involvement consists of dry, hyperkeratotic, scaly skin, sparse and curly hair, and cavernous hemangioma. Most patients have a congenital heart defect, most commonly pulmonic stenosis and hypertrophic cardiomyopathy. ► https://www.cfcsyndrome.org/fact-sheet

- Epilepsy and recurrent seizures (G40 ICD10): ~200 seizures per month w/ anti-seizure Rx; three severe seizure hospitalizations per month.
- Severe mental impairment (*F79 ICD10*)
- Osteopenia (M85.80 ICD10)

Medical History

- Normal 9-month vaginal birth; 5 months developmental delay, 9 months diagnosed "failure to thrive"; started tube feeding; residential care at home parents
- Diet History: Tube feeding Infant Formula until 3 years old; 3–20 years old received Boost™ tube feeding; weight 78–80 lb. bedridden, Birth lab significant for hypercalcemia 10.9 HI (<10). No PTH was ordered. Hypothyroid Day 1 screen WNL.

Signs and Symptoms

- No eye contact
- Appears pain when touching arms and hands during bathing
- Tube feeding tolerated

Lab History: Significant Findings

- Methylmalonic acid 861 very HI (B12 functional marker)
- B12, serum >2000 pg/mL
- Lipid Panel: Total Cholesterol 128 mg/dL; LDL 55 mg/dL: Low-end
- Ferritin 24 – Low End
- Vitamin D >120
- GGT 88 HI (ideal <10) [can be suggestive of toxcity and/or low glutathione status]
- Differential: WBC 6.04; Neutrophils 40.2 low end/Lymphocytes 44.7 HI
- Specialty Lab: RBC Fatty acid analysis: Very low arachidonic acid, GLA, DGLA, Hi EPA, Hi DHA
- Specialty Lab: lymphocyte micronutrient analysis: LOW: vitamin D, B12, A, carnitine, zinc, magnesium, choline

PLAN: Complex Neurological Condition
Three-Month Plan

- Retest previous abnormal tests
- Monitor symptoms /behavior – report TF tolerance and any changes weekly
- Mother requested investigating possibility that AM and mother were hypothyroid - mother exploring possibility AM was hypothyroid and infant screening was done day of birth negative, but protocol is to be tested day 3 after birth. Early screening may have missed hypothyroid condition.

Three-Month Follow-up

- Review new lab. WNL: B12, serum, methylmalonic acid ABNORMAL:, +ANA Titer, +++ EBV, Total + IgG/+IgE, carnitine panel: low,
- Seizures reduced 50–60% no hospital trips, reduced anti-seizure Rx
- Eye contact; no pain appearance touching during bathing.

Nutrition Assessment Metabolic Priorities

- B12 deficiency; specific for adenosylcobalamin B12 2000 µg/day with L-5-MTHF (bioactive folate)
- Request doctor rule out subclinical infection with further viral/bacterial panel
- Depleted vitamin/minerals: D, A, B12, -5-MTHF, carnitine, phosphatidylcholine/phosphatidylethanolamine, Linoleic Acid,
- Home tube feeding Lipid Liquid Meal recipe 2 quarts
- 2 scoop vegan or beef protein powder
- 48 oz unsweetened almond or coconut milk; add water to achieve TF consistency
- 2 tsp Phosphotidylcholine/Phosphotidylethanolamine (mitochondrial support)
- 2 tsp evening primrose oil (GLA)
- Multivitamin/mineral powder 2 scoop (bioactive B vitamin forms)
- Active B12 w (adenosylcobalamin B12) w/ L-5-MTHF 1000 µg 1 tab in TF
- 1–500 mg L-carnitine – open capsule into TF
- 1 blanched egg yolk
- Blend and administer within 24 hours, refrigerate

Outcome 14 Months and beyond:

- Five months free of hospitalization due to severe seizures
- Eye contact daily
- Reach for objects
- Adult school; at 14 months mouthed quietly to Mom "I love you".
- Continues Lipid Shake daily, sometimes adds healthy variety of foods.

11.12 Conclusion

Lipids are the molecular components that comprise the *lipidome*—the complete lipid profile within the membrane, cell, tissue, or organism. The lipidome is in the dynamic metabolism of life expressing the genetic information in the DNA book of life. The membrane houses the receptors that receive information and direct the biochemistry to survive. The two functions of the lipids that can be modulated by nutrition therapy are membrane structure and inflammation control.

This chapter has described the association between a person's nutritional status and their vulnerability for impaired fatty acid status. Nutritional status of an individual is a determinant of how well their body can respond to and resolve an infection returning it to a state of wellness.

It is important to consider an individual's fatty acid status for several chronic disease conditions. Pathophysiology of chronic disease reveals its contrast to acute disease by its long-term development, often asymptomatic and not recognized. Subclinical chronic disease progression can "smolder" unrecognized for many years, even beginning in-utero and childhood. This biological stress often goes undiagnosed or with the patient being unaware of the significance. This chapter provides knowledge of lipid metabolism, as it relates to membrane function, the assessment of lipid imbalances, and specific membrane and anti-inflammatory nutrients that can contribute to targeted intervention and optimal health [87].

12.1 Introduction

Cellular structure is the foundation on which biochemical and energetic functions occur. The vast number of processes that our tissues and organs are capable of accomplishing derives from the basic molecular structures of which they are composed. In other words, unless the individual cells, their organelles, and their membranes are supported by the proper nutrients and suitable environment, the body systems they comprise will be unable to function optimally.

Damage to the cellular structure can result in a multitude of dysfunctions. Dietary and lifestyle choices can influence the overall health of our bodies down to the structure of our cell membranes. Maintaining a diet full of nutrients such as essential omega-3s and omega-6s, and even cholesterol, can help structurally stabilize our cell membranes as well as reduce the susceptibility to leakage of beneficial nutrients out of the cell.

In any patient presenting with a constellation of symptoms, a clinician should ask if there is a structure, or structures, that should be evaluated and supported. When developing a plan to support a particular structure, both the clinician and the patient must be aware that this modification may take months to years. Short- and long-term goals should be established, and monitoring the structural health and integrity should be done periodically.

There are key questions to ask when evaluating for structure, including:

- What structures are compromised in my patient in relationship to their symptoms or aging process?
- Is there a cell type, organelle, membrane, tissue, organ, or other structure that is related to my patient's symptoms?
- From the cellular to the tissue/organ/skeletal level, what is the possible structural compromise/pathology?
- What is the level of function and dysfunction of these structures?
- If there is degeneration in the structure, what is the extent of degeneration?
- Is regeneration of this structure possible?
- What support could I give these structures?
- Can function be augmented without improving structure?
- What structural barriers (intestinal wall, blood–brain barrier, lung barrier, etc.) are compromised in my patient??
- Is there research to show that the membrane, tissue, or organ can be supported and improved in its structure and function?
- How much of a change in this structure and function can my intervention make?
- How long will it take to make changes in this structure?
- What are the most important interventions to improve the health of the cell, tissue, or system, and what is an estimated cost of these interventions?
- Can I evaluate the integrity of these structures with a lab test, imaging study, or assessment of nutrition status?

In this chapter, we will discuss structure, starting at the cell membrane and moving to musculoskeletal and other tissues, while examining key structural questions.

12.2 Part I: Membrane Structure

12.2.1 Introduction

The membranes of our cells are important in that their integrity is critical for cellular function. For this purpose, cell membranes are comprised of a plethora of components necessary to not only hold all of the vital cellular structures in but also have the ability to be selectively permeable in regard to what solutes can pass through the membrane, as well as provide a location for necessary biological reactions to occur. The central component that is arguably the most vital for the cell membrane to fulfill its specific demands are lipids.

12.2.2 Biological Structure

Our cell membranes are made up of two stacked sheets of lipids, known as the lipid bilayer, with proteins intermittently embedded within, at a ratio of about 1:1. Carbohydrates are also incorporated throughout, but they only constitute about 10% of the membrane [1]. Phospholipids are amphipathic molecules, meaning they have a nonpolar head that is hydrophobic attached by a phosphate ester bond to two polar tails that are hydrophilic. The lipids arrange themselves in such a way that hides their hydrophobic end from the surrounding water in our tissues and presents their hydrophilic end, forming a curved bilayer structure appearing as a circle. Their properties make them insoluble in water, proving them to be an effective candidate for protecting the fragile internal components of our cells from our surrounding fluids. Besides acting as a protective barrier, the membrane also provides an anchor for the internal cytoskeleton to grasp onto, creating a place for cell adhesion, allowing groups of cells to bind together to form tissues [2]. Another important function of the membrane is to act as a surface for important biological reactions to occur, including oxidative phosphorylation on the inner mitochondrial membrane [3]. The membrane also is home to numerous receptors.

Membranes thereby become the most abundant cellular structure in all living matter. They can be considered as nature's preferred mode of microencapsulation technology, developed as means of compartmentalizing living matter and protecting the genetic material. The biological membrane is the essential capsule of life. Many important biological processes in the cell either take place at membranes or are mediated by membranes, such as transport, growth, neural function, immunological response, signaling, and enzymatic activity. An important function of the lipid bilayer is to act as a passive permeability barrier to ions and other molecular substances and leave the transmembrane transport to active carriers and channels [1] (Fig. 12.1).

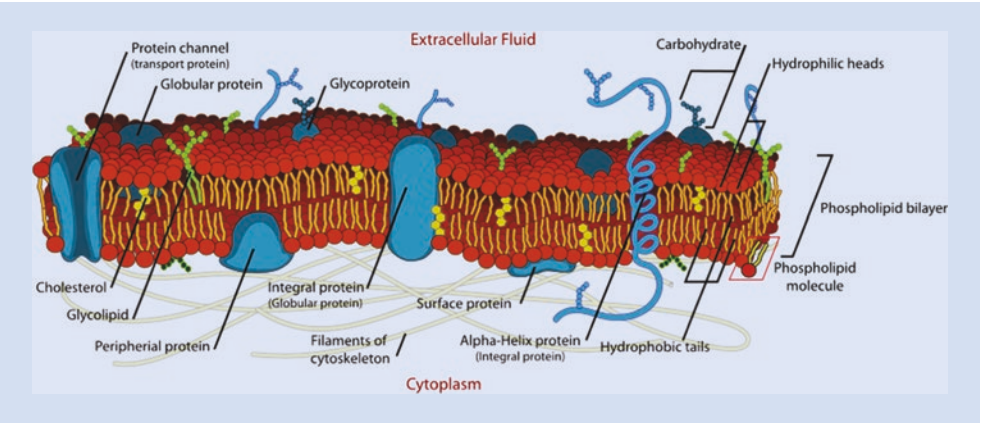

Fig. 12.1 Schematic model of the plasma membrane of a eukaryotic cell which highlights the membrane as a composite of a central lipid bilayer sandwiched between the carbohydrate glycocalyx (which consist of polysaccharides) on the outside and the rubber-like cytoskeleton (which is a polymeric protein network) on the inside. Intercalated in the lipid bilayer are shown various integral proteins and polypeptides. The membrane is subject to undulations and the lipid bilayer displays lateral heterogeneity, lipid domain formation, and thickness variations close to the integral proteins. Whereas the lipid molecules in this representation are given with some structural details, the membrane-associated proteins remain fairly featureless. In order to capture many different features in the same illustration, the different membrane components are not drawn to scale. (Reprinted from Benton et al. [78]. With permission from Wolters Kluwer Health, Inc.)

In order for a cell membrane, or a lipid bilayer, to function optimally, it requires a set of conditions that ultimately make the completion of the membrane's tasks easier and more likely to occur properly. Lipid bilayers are soft and pliable while retaining a structure in order to bend without breaking down [1]. In addition, they exist in specific structural compositions so that they are stable enough to hold their shape. The stability of the membranes is largely due to adequate cholesterol molecules embedded throughout the membrane as an important structure builder in all cells, making the membrane thicker and less "leaky." In addition, cholesterol is a basic unit of some vitamins and hormones. All animals contain cholesterol in the plasma membranes in amounts from 30% to 50% of total lipids. The organelle membranes contain very little: mitochondrial membranes less than 5%, Golgi membranes about 8%, and ER membranes around 10% [4]. Finally, membranes are particularly selective in the way that the individual lipids and transport proteins are organized within the bilayer so that they can control their permeability efficiently.

The length and degree of saturation of fatty acid chains in the phospholipids affects membrane properties, specifically fluidity. The breakdown of the different types of fats found in the membrane is about one-third cholesterol, one-third unsaturated fatty acids, and one-third saturated fatty acids, but these ratios fluctuate depending on other variables [5]. Unsaturation creates a kink in the fatty acid chain, which prevents the fatty acids from packing together as tightly, therefore increasing the fluidity of the membrane. The presence of cholesterol in the membrane also affects fluidity, which will be discussed later in this section. Membrane fluidity is carefully regulated since enzymatic activity as well as transport processes can stop working if the viscosity of the membrane gets too high. A common tool used in IFMNT practice is the bioelectric impedance analysis equipment measuring the phase angle, often described as a marker of cell membrane fluidity and nutritional status.

The lipid composition of the two monolayers of the lipid bilayer are characteristically different from one another. The phospholipids phosphatidylcholine (PC) and sphingomyelin, as well as cholesterol and glycolipids, are predominantly found on the outer monolayer. Phosphatidylethanolamine (PE) and phosphatidylserine (PS) are primarily found on the inner monolayer, facing the inside of the cell. The presence of PS on the inner monolayer creates a difference in charges between the two monolayers [2]. This is especially important in electrically excitable cells, like neurons and muscle cells, where changes in membrane potential are used to generate signals within the cell or to the neighboring cells.

12.2.2.1 Phosphatidylcholine

Phosphatidylcholine (PC) is the most common phospholipid contained in the bilayer cell membrane, and accounts for over half of the total membrane phospholipids primarily in the outer leaflet [6]. It is an essential nutrient that is consumed regularly in our diet, from eggs, raw dairy, and some cruciferous vegetables, as well as available as a dietary supplement or medical intravaneous infusion. PC is used to help maintain cell structure and aid in signaling, particularly in neurons [4, 6] (Fig. 12.2). It organizes itself spontaneously into the bilayer, providing the membrane with the bulk of its structure. Besides playing an essential role in the cell membrane, phosphatidylcholine is also necessary for the secretion of important plasma lipoproteins VLDL and HDL, since both of these molecules are surrounded by a phospholipid monolayer [6]. Phosphatidylcholine is also secreted into bile, where it assists with the digestion of dietary fat [6].

Substituent	Chemical formula[a]	Polar head group name	Ab[b]
Hydrogen	–H	Phosphatidic acid	PA
Choline	$-CH_2CH_2N(CH_3)_3^+$	Phosphatidylcholine	PC
Ethanolamine	$-CH_2CH_2NH_3^+$	Phosphatidylethanolamine	PE
Serine	$-CH_2CH(NH_3)COO^-$	Phosphatidylserine	PS
Glycerol	$-CH_2CH(OH)CH_2OH$	Phosphatidylglycerol	PG
myo-inositol		Phosphatidylinositol	PI

[a]Chemical formula for the substituent linked to the phosphate group at position 3 of the glycerol moiety
[b]Abbreviation for the polar head group nomenclature

Fig. 12.2 Lipid polar head of phospholipid groups. (Reprinted from Mouritsen et al. [4]. With permission from Springer Nature)

12.2.2.2 Phosphatidylethanolamine

Phosphatidylethanolamine (PE) comprises about 25% of the phospholipids in most membranes, with about 37% PE in the inner mitochondrial membrane [7]. This percentage can be up to 45% in nervous tissue, such as neural tissue, nerves, white matter in the brain, and cells of the spinal cord [7]. It is involved in cell fusion and division as well as regulating membrane curvature [8]. PE contains a polar head group, which in turn lowers the melting point of the phospholipid, contributing to the viscosity and fluidity of the lipid membrane. Beyond the membrane, phosphatidylethanolamine is also involved in blood clotting and the secretion of lipoproteins in the liver [9].

12.2.2.3 Phosphatidylserine

Constituting 3–10% of the total lipids within the cell, phosphatidylserine (PS) plays an important role in cell-to-cell signaling and is involved in the proper localization and activation of many intracellular proteins [10]. The location of PS within the membrane directly affects the health of the cell. PS is located on the inner monolayer, and therefore faces the inside of the cell [10]. During the immune system response, apoptotic lymphocytes bring PS to the surface of the outer monolayer, where it becomes a signal for phagocytosis by activated macrophages with the process of autophagy and the cell is cleared from circulation [11]. This makes the differences between the two monolayers critical to the health and survival of the cell. Proper biological function depends on the elimination of unwanted, useless cells often referred to as "cellular debris"; therefore, the mechanisms of apoptotic cell recognition using PS and the subsequent removal by phagolysosomes are important in order to prevent excess inflammation and uncontrolled cell lysis [11]. The decision to use PS as a dietary supplement should consider the individual's membrane status and adequacy of other important phospholipids like PC and PE.

12.2.2.4 Cholesterol

Cholesterol is a vital component of all biological membranes. In fact, cholesterol is the most abundant type of lipid in our membranes, accounting for 30–50% of the lipid molecules [1]. Cholesterol is a lipid that is structurally very different from the phospholipids that are found in the membrane. It has a steroid ring structure as well as a hydroxyl group as its polar head. This structural difference makes cholesterol bulkier than its surrounding lipids, promoting stability in membrane shape. The presence of cholesterol in the membrane also makes the membrane less pliable, less susceptible to compression, and leads to a thickening of the membrane. This rigidity allows the membrane to maintain its integrity and shape, as well as making the membrane tighter and therefore less permeable.

In addition to providing stability, cholesterol also plays a vital role in protecting the cell membrane from nutrients that we consume that could be harmful to the cell. Many pharmaceutical drugs are comprised of amphiphilic molecules, meaning that their target sites within the body are places that are composed of similar molecules, that is, lipid bilayers. Such drugs that are intended to target membranes include, but are not limited to, antipsychotics, antitumoral drugs, antidepressants, tranquilizers, antihistamines, antifungals, and analgesics. As these drugs interact with the membrane, they cause it to lose stability, making it susceptible to compression and leakage. In addition to amphiphilic drugs, ethanol-based alcohols can also have a detrimental effect on the lipid bilayers of our membranes. Ethanol congregates on the glycerol backbone of the lipid bilayer, creating a buildup of pressure on the membrane. However, cholesterol can help protect our membranes from damage due to medication and alcohol consumption. The presence of cholesterol can help redistribute the pressure that ethanol places on the glycerol backbone of the lipids in the bilayer. In addition, due to its bulkiness in size and structure, it can help squeeze ethanol and other amphiphilic drugs out of the membrane.

12.2.2.5 Proteins

Embedded throughout the lipid bilayer are peripheral (temporary) and integral (permanent) proteins. Peripheral membrane proteins are almost exclusively found on the cytosolic-facing monolayer. Proteins have many metabolic functions in the cell, including providing structure, transferring molecules across the membrane in and out of the cell,

acting as enzymes in biological processes, and making up receptors for molecules outside the cell, such as hormones.

12.2.2.6 Carbohydrates

Carbohydrates are also included in the structure and function of the membrane, but to a much smaller degree than fats and proteins. They are only present on the outer monolayer, facing the extracellular environment. Their function is to act as signaling molecules, allowing cells to be recognized by other cells. They do not exist in the membrane as sole molecules, but instead are attached to other proteins or lipids, creating glycoproteins and glycolipids.

All of these membrane components ultimately allow the cell to function optimally, which in turn allows the tissues and organs that these cells comprise to work effectively. With a properly working cell membrane, essential nutrients are able to be adequately absorbed into tissues, while harmful waste is removed and excreted. Cells are able to effectively communicate with one another, a necessity for cells to work together to form tissues. Hormone sensitivity and utilization increases when the proteins that form hormone receptors on the membrane are intact.

12.3 Part II: Dietary and Lifestyle Influences

12.3.1 Introduction

The overall health of our cell membranes, in addition to their ability to function at maximum capacity, is largely dependent on one's diet and lifestyle habits. However, many are unaware that even our most subtle nutritional choices have the power to influence our bodies down to the molecular level, particularly in regard to the state of our cell membranes. Knowing how vital the role of a cell membrane is in the grand scheme of the human body makes knowing what causes harm to these membranes equally as important.

12.3.2 Pathophysiology

Cell membrane damage occurs in a variety of different mechanisms, all of which can be detrimental to the body at the cellular and macromolecular levels. Considering cell membranes consist of a variety of different lipids and proteins, it is not difficult for one element to damage a vast majority of the phospholipid bilayer membrane once it has been introduced into just a portion of the membrane.

Since cell membranes are composed of over 50% lipids, consuming a diet that is low in fat is damaging to the membrane. A diet rich in monounsaturated fatty acids and essential fatty acids, especially a balance of the essential omega-3 and omega-6s producing the eicosanoid metabolites, while limiting long-chain saturated fat and avoiding ultra-processed vegetable oils with trans-fat and acrylamides supports healthy cell membranes [12]. The ratio of omega-3s to omega-6s of 5:1 to 1:1 should be properly maintained in balance, since a higher ratio of omega-3s in the body leads to the production of anti-inflammatory molecules, whereas an abundance of omega-6s leads to the production of inflammatory molecules [12]. Chronic stressors can also cause inflammation in the body, which can lead to programmed cell death, so it is important to manage stress.

In addition to lifestyle and dietary habits, certain inevitable biological processes have the ability to naturally damage cell membranes as well. Aging unfortunately has proven to have a negative influence on cell membrane health. As the human body ages, the amount of phosphatidylcholine that comprises our cell membranes decreases as the amount of cholesterol and sphingomyelin increases. Phosphatidylcholine is one of several phospholipids in the membrane that contribute to its fluidity and ability to react to differing internal conditions. When there is a low amount of phosphatidylcholine, cell membranes are more rigid, which ultimately diminishes their permeability and movement properties.

Many clinical conditions can also be attributed to membrane phospholipid oxidative damage. Damage to the membrane is destructive to the health of the overall cell and therefore harmful to the health of tissues and organs that these cells comprise. The body regulates each system and reaction under tight control to minimize any unintended consequences, but even under normal biological conditions, there is some level of uncontrolled reactions occurring, resulting in inadvertent outcomes. The production of reactive oxygen species is a prime example of unintended consequences formed by normal physiological processes.

12.3.2.1 Reactive Oxygen Species

Reactive oxygen species (ROS) are occasionally formed during the metabolism of molecular oxygen [13]. This is particularly present in the mitochondria during oxidative phosphorylation. The damage that reactive oxygen species cause can be detrimental to the cell's ability to function properly. It is important to limit the production of ROS, although some will always be generated as a natural byproduct of normal cell processes.

The properties of phospholipids as well as the chemical reactivity of fatty acids in the bilayer make the cell membrane an easy target for oxidation [14]. Oxygen and free radicals are more soluble in the fluid lipid bilayer than in the aqueous environment inside and out of the cell [14]. This attracts oxygen molecules to the bilayer, increasing the chances for oxidative damage [14]. Polyunsaturated fatty acids are extremely sensitive to oxygen, and the number of double bonds in their structure increases their susceptibility to attack by reactive oxygen [14]. Unsaturated fatty acids comprise about a third of the total fat content of the cell membrane, and this creates a large target for oxidation.

12.3.2.2 Mitochondria

In order to properly illustrate the impact that cell membrane health has on greater biological processes, we will explore the mitochondria as an example of an organelle whose energy production relies entirely on the proper function of its membrane.

Mitochondria are known as the powerhouse of the cell. Though other cellular processes may produce small amounts of adenosine triphosphate (ATP), or the cellular form of energy, the majority of it comes from the mitochondria via oxidative phosphorylation. The process of producing ATP occurs specifically within the inner mitochondrial membrane, not the cytoplasm [15]. Healthy and high-functioning mitochondria are imperative for the overall function of the cell and ultimately the greater biological structure because of its energy-producing properties.

Mitochondria contain two membranes, the inner and the outer mitochondrial membranes. This distinct structure provides plenty of space for mitochondria to function optimally. The outer mitochondrial membrane contains an abundance of lipids, while the inner mitochondrial membrane contains only about 20% lipids and instead has an abundance of proteins and phospholipids [16]. Oxidative phosphorylation occurs within the inner membrane, a process laden with enzymes (proteins) and other complexes. The membranes of mitochondria contain the same phospholipids as the cell membrane, with phosphatidylcholine dominating the outer membrane, and phosphatidylethanolamine dominating the inner mitochondrial membrane with lessor amounts of phosphatidylinositol, phosphotidic acid and phosphatidylserine, while also containing a mitochondria-specific phospholipid, cardiolipin, with a primary role in the mechanism of apoptosis [17]. The mitochondrial membranes contain low levels of cholesterol and sphingomyelin compared to the cell membrane [15].

There are many factors that can cause immense damage to the mitochondria. These include, but are not limited to, statin drugs, antibiotics, chronic stress, age, cigarettes, hyperglycemia, excessive arachidonic acid, excessive exercise, persistent organic pollutants (POPs), and heavy metals [18–22]. These all contribute to the formation of reactive oxygen species, but the greatest generator of ROS is mitochondrial oxidative phosphorylation, with about 1–5% of the oxygen consumed by the mitochondria converted to ROS. Oxidative phosphorylation includes the conversion of nutrient-derived substrates into ATP. This takes place on the inner mitochondrial membrane, through the action of five respiratory enzyme complexes. The main sites for ROS production are on complexes I and III of the mitochondrial electron transport chain, where electrons are being transferred from different oxygen molecules [23]. The desired outcome from this electron transfer is the generation of ATP to provide energy for cells. However, in some cases, the transfer can inadvertently generate superoxide anion, a dangerous ROS. Superoxide anion is produced from the one-electron reduction of oxygen and is a precursor for most reactive oxygen species.

The presence of cardiolipin, a phospholipid found in the inner mitochondrial membrane, increases the mitochondria's susceptibility to attack by reactive oxygen species. Cardiolipin is required for the electron transport chain (ETC) by connecting the four ETC complexes as well as supplying protons for ATP synthase [24]. In the ETC, hydrogen ions are pumped from the matrix of the mitochondria across the complexes located on the inner mitochondrial membrane (IMM) into the intermembrane space, creating a higher concentration of hydrogen ions within the intermembrane space than in the matrix. This gives the intermembrane space a positive charge and the matrix a negative charge, creating an electrochemical gradient. The IMM is not permeable to ions, preventing the abundance of hydrogen ions within the intermembrane space from crossing the IMM. With the help of ATP synthase, hydrogen ions are transported into the matrix of the mitochondria. The energy that is generated from this flow of ions against the electrochemical gradient phosphorylates adenosine diphosphate (ADP) into adenosine triphosphate, resulting in cellular energy.

While cardiolipin in the inner mitochondrial membrane is crucial for the generation of ATP, its proximity to the ROS that are generated within the mitochondria also makes it an easy target for oxidative damage. When cardiolipin and other membrane phospholipids are damaged by oxidation, they no longer form a tight ionic barrier from surrounding protons and ions, allowing these charged molecules to freely move across the membrane. This weakens the electrochemical gradient and therefore results in a loss of electron transport and therefore diminished cellular energy production.

It is imperative to protect mitochondria from damage, as harm to mitochondrial health can lead to impairment in their function. The more damage to the mitochondria, the less efficient they are at generating ATP, and therefore the more ROS they produce. Consequently, the more ROS that is produced, the more damage occurs, resulting in a vicious cycle of deterioration. Endogenous and supplemental CoQ10 are known protectors of the delicate mitochondria from excess ROS exposure.

There are many diseases and illnesses that can be traced back to membrane damage or dysfunction. Fatigue is often the first indication of cell damage, due to membrane malfunction. When the membrane is damaged, cells may not be able to signal efficiently and hormone receptors may not work as well, resulting in either the overstimulation of hormone targets or the lack of hormone activity.

Mitochondrial dysfunction is characterized by the loss of efficiency of the electron transport chain and therefore the reduction in synthesis of ATP [25]. This decrease in energy production can lead to symptoms of fatigue. While this seems like an obvious, expected outcome, there are numerous other illnesses that can result from dysfunctional mitochondria. Among these are neurodegenerative disorders, including Amyotrophic Lateral Sclerosis (ALS) (► Chap. 50), Alzheimer's, Parkinson's, Huntington's, bipolar, and autism spectrum disorders (► Chap. 31), as well as cardiovascular disorders (► Chap. 47), such as diabetes, metabolic syndrome, atherosclerosis, and obesity [25]. Mitochondrial dysfunction can also lead to gastrointestinal and musculoskeletal disorders, including fibromyalgia and muscular atrophy, as well as chronic infections and even cancer [25].

12.3.3 Evaluation/Assessment

There are many lab tests that can be used to determine cell and mitochondrial function. Some tests are used to determine how well certain cell components are working, including blood assessments of lactate and pyruvate levels, which can reflect how well mitochondria are oxidizing pyruvate [12]. An increase in lactate compared to pyruvate indicates a problem with pyruvate metabolism by the mitochondria. Other tests look for damaged cell components, which can be an indicator of oxidative damage. Two useful assessments for detecting oxidative damage include urinary analysis of 8-oxo-7, 8-dihydro-2′-deoxyguanosine, an oxidized nucleotide of DNA, which can be used to detect damaged nuclear or mitochondrial DNA [26]. Another test includes the serum level of the enzyme gamma-glutamyl transferase (GGT) [27]. Assessing antioxidant levels, including superoxide dismutase and catalase, can also be beneficial in determining the effects of ROS in the body. The organic acid test is another useful tool that evaluates for cell function by detecting blockages in the citric acid cycle.

12.3.4 Prevention/Treatment

There are a multitude of nutritional components that can enhance cellular membrane health. Since the cell membrane is made up primarily of lipids, consuming adequate amounts of fat in the diet is essential to maintaining proper structure and therefore optimal function of the cell. The current Acceptable Macronutrient Distribution Range (AMDR) for adults suggests that 25–35% of total calories should come from fat. Good sources include fatty fish, nuts, seeds, avocados, and oils.

12.3.4.1 Antioxidants

Considering reactive oxidants are a major detriment to the membrane, serious damage can be prevented by consuming adequate amounts of antioxidants, including vitamins E and C. The lipophilic properties of vitamin E enable it to fit comfortably in the membrane, protecting the phospholipids' unsaturated hydrophilic ends from free radical attachment and damage. These nutrients are critical in preventing initial oxidation, subsequent peroxidation, and the resulting oxidative chain reactions. The current Recommended Dietary Allowance (RDA) for vitamin E, found in nuts, seeds, and safflower oil, is 15 mg/day (or 22.5 IU/day) for adult men and women. It is not unreasonable to take 200–400 IU of mixed tocopherols with tocotrienols daily to protect cell membranes. The current RDA for vitamin C is 90 mg/day for men and 75 mg/day for women and the highest dietary sources include bell peppers, oranges, kiwifruit, and strawberries. Since vitamin C has a reasonably short half-life in the body, it would be reasonable to dose vitamin C two to three times a day. The RDA is recommended for the prevention of scurvy, not for the protection of cell membranes, therefore a good recommendation can be approximately 250 mg of vitamin C two to three times a day. Along with antioxidants, the cholesterol content of the membrane affects how phospholipids are packed in the membrane and therefore can affect the efficiency of free radical propagation through the lipid bilayer, so it is important to not shy away from it. There is no current RDA for cholesterol since our bodies synthesize it naturally. Cholesterol in the diet comes from animal sources, particularly meat, poultry, eggs, and dairy products.

12.3.4.2 CoQ10

Coenzyme Q10 (CoQ10) is a vital cofactor in the electron transport chain, facilitating the transfer of electrons between complexes I and II by acting as an electron donor or acceptor. In its oxidized form, ubiquinone, it accepts an electron from a molecule in the electron transport chain and is reduced to ubiquinol. When the reduced ubiquinol donates an electron to a neighboring molecule, it returns to its oxidized form of ubiquinone. The reduction and oxidation reactions that CoQ10 constantly undergoes make it a valuable antioxidant, quenching the harmful reactive oxygen species that are spontaneously generated during oxidative phosphorylation. CoQ10 also transfers protons across the inner mitochondrial membrane, creating a proton gradient, aiding in the generation of ATP. CoQ10 is the only fat-soluble antioxidant that can be generated by the body, and therefore may not need to be obtained from the diet or as a supplement. There is no RDA for CoQ10, however supplementation is recommended in order to treat a number of mitochondria-related conditions, including Parkinson's disease, migraines, and muscular dystrophy. The recommended supplemented intake of CoQ10 ranges from 100 mg a day to upwards of 300 mg a day, depending on the condition [28]. There are many foods that are high in this nutrient, particularly chlorophyll-rich vegetables, such as dark, leafy greens, fresh herbs, broccoli, peas, and asparagus, however it may be difficult to get adequate CoQ10 from diet alone when dealing with neurodegenerative or other disorders.

12.3.4.3 Lipoic Acid

Lipoic acid is another vital cofactor in mitochondria, aiding in the conversion of food into useful energy, reacting with reactive oxygen species, and protecting membranes by reacting with vitamin C and glutathione to recycle vitamin E [29, 30]. In these ways, it acts as an antioxidant, protecting mitochondria from ROS damage. Lipoic acid is synthesized in our bodies and studies have found that only 30–40% of supplemented lipoic acid is absorbed, meaning there is no recommended dietary allowance for lipoic acid [31]. Dietary sources include protein-rich foods, such as meat and some vegetables, including broccoli and spinach. Alpha lipoic acid may be more effective in reducing oxidative damage if taken it its R form, as R-ALA. Consider supplementing R-ALA in chronic neurological conditions or in other conditions in which oxidative stress is thought to be a significant issue.

12.3.4.4 Phosphotidylethanolamine

Primary mitochondrial inner membrane component influencing production of cardiolipin. PE is the second most abundant phospholipid in metabolism and a precursor to production of the important primary phospholipid PC. PE has many other critical functional roles in membrane metabolism including protein integration into membranes, autophagy, cell division, mitochondrial stability, as well as determing membrane conformational changes. Nutritional status of PE is dependent on the intake of the essential nutrient, choline.

12.3.4.5 L-carnitine

L-carnitine helps transport fatty acids into the mitochondria where they are burned as fuel during beta oxidation. The body sufficiently synthesizes and reabsorbs L-carnitine at a rate of about 95%, so supplementing this nutrient is not usually needed, unless severe deficiencies occur. Some dietary sources include meat, poultry, fish, and dairy products in high amounts, as well as fruits, vegetables, and grains in relatively small amounts. Research suggests that a therapeutic dose of L-carnitine to support mitochondria is 1000 mg three times a day, along with the supplementation of 400 mg of CoQ10 a day to prevent oxidative damage to mitochondria during oxidative phosphorylation [32].

12.3.4.6 Mitochondrial Biogenesis

Besides slowing the loss of mitochondria, it is also important to increase the number of functioning mitochondria and their size in various tissues. Type 1 and type 2 diabetic patients have fewer mitochondria as well as less efficient energy production in their mitochondria. This population should be given suggestions to augment mitochondrial mass and function. As people age, they accumulate higher amounts of mitochondrial DNA damage and this, along with blunted mitochondrial biogenesis, leads to a decline in the numbers of functioning mitochondria, especially in muscle cells. Type 1 muscle fibers, known as endurance or slow twitch, have a higher content of mitochondria than fast twitch fibers. As people age, the density of mitochondria decreases in their muscles as well as in other tissues. Aerobic exercise completed regularly can lead to increased density of mitochondria in muscle. Another method of mitochondrial biogenesis includes intermittent fasting; therefore, patients should be advised to not eat for 12–13 hours from the time of their evening meal to breakfast.

Resveratrol is a sirtuin activator and can be used as a supplement to augment mitochondrial mass. Researchers have determined that in order for sirtuin activators, like resveratrol and exercise, to adequately support healthy mitochondrial function, adequate NAD+ levels are necessary, and nicotinamide riboside has been shown to effectively increase NAD+ levels in humans [33]. Nicotinamide riboside can be supplemented in doses of 125–250 mg twice a day, along with 125 mg of resveratrol [34]. Pyrroloquinoline quinone (PQQ) is an antioxidant that can decrease mitochondrial oxidative damage, as well as augment mitochondrial biogenesis. Doses of 20 mg have been used in studies [35]. It has also been shown to have synergistic effects when combined with 300 mg of CoQ10 [35]. PQQ may be particularly relevant when treating neurological diseases, such as Parkinson's and Alzheimer's. PQQ can also be used to enhance cardiac function as well as decrease mitochondrial damage after an MI or when a patient is in heart failure.

Improving or maintaining mitochondrial health is key to overall wellbeing, particularly in treating chronic fatigue and many degenerative neurological conditions. The mitochondrial membrane can be supported with omega-3 fatty acids, and it may be worthwhile to use supplemental phosphatidylserine as well as phosphatidylcholine. Reducing exposure to damage caused by free radicals can be accomplished by consuming adequate antioxidants, while minimizing exposure to mitochondrial toxins, such as statin drugs and persistent organic pollutants, is an important first step in prevention, and can be helped by purchasing most, if not all, foods as organic. Promoting mitochondrial biogenesis will increase the mass of mitochondria in tissues.

The keys to focus on when it comes to maintaining mitochondrial health include reducing exposure to damaging factors, consuming nutrients that are beneficial to mitochondrial function, and preventing oxidative damage in the first place. Avoiding mitochondrial toxins, such as statin drugs, POPs, and chronic stress, while also consuming nutrients that are beneficial to mitochondrial function, such as CoQ10 and antioxidants, means that oxidative damage to the mitochondria can be reduced and therefore the diseases associated with mitochondrial dysfunction can be prevented.

12.4 Part III: Organ Structure and Function

12.4.1 Introduction

Disturbances to our major tissues and organs, especially those that inhibit their inability to function optimally, are often a result of dietary and lifestyle influences that impact cellular function. The eyes, the brain, and the gastrointestinal tract are three crucial components of the body in which any change to structure causes noticeable dysfunction. Since the ability of a tissue or organ to function at its full capacity relies on the basic cellular structures of which it is comprised, it is imperative that we analyze the components that have the means of diminishing or enhancing individual cells within these major systems.

12.4.2 Eye

12.4.2.1 Biological Structure

The eye is a prime example of how understanding structure allows us to understand the pathophysiology associated with this organ. The main disease affecting the eye is age-related macular degeneration (AMD), which is characterized by the gradual loss of central vision, particularly in those over the age of 55. The macula is a small, 3–5.5 mm area within the retina, containing the fovea at its center. It is a multilayered structure that is made up of millions of light-sensing cells that provide central vision. The macula and fovea are rich in

photoreceptive cone cells, which are responsible for light sensing. The retina also contains the retinal pigment epithelium, which, among other functions, helps transport nutrients and water, is involved in the visual cycle, as well as protects the eye by absorbing light and preventing photo-oxidation, via the action of tight junctions [36].

12.4.2.2 Pathophysiology

There are many possible physiologic changes to the different structure in the eye that can lead to the development of age-related macular degeneration.

Dry Form

As the eye ages, the retina's ability to receive proper nourishment is hindered, leading to the accumulation of waste, and resulting amorphous deposits, or drusen, in the retina [37]. This causes the retinal pigment epithelium cells to degenerate and atrophy, resulting in the loss of central vision. This is classified as the dry, or atrophic, form of AMD. This form slowly progresses and can lead to total blindness in a span of 5–10 years [37].

Wet Form

The integrity of the retina can be attributed to the Bruch's membrane, which is the basal lamina of the retinal pigment epithelium, separating the retina and the choroid [38]. When the Bruch's membrane is broken, this can allow abnormal blood vessels to grow underneath the macula and retina [38]. When these blood vessels bleed, the macula bulges out, causing distorted vision. Resulting vision loss is rapid. This severe form of AMD is called wet, or exudative, and only makes up about 10–15% of AMD cases [39].

Reactive Oxygen Species

The constant exposure to light that the eyes are faced with leads to a high chance of photo-oxidation. The constant exposure to oxygen leads to a high rate of generation of reactive oxygen species. The role of antioxidants, both enzymatic (i.e., superoxide dismutase, catalase) and non-enzymatic (i.e., carotenoids lutein and zeaxanthin), are vital to prevent ROS damage.

12.4.2.3 Evaluation/Assessment

There are many risk factors for age-related macular degeneration, and fortunately many of them are modifiable and therefore can prevent or help delay the onset of the disease. These include smoking, elevated homocysteine levels, altered RBC fatty acid balance, obesity, and other cardiovascular-related risks, including hypertension, elevated total cholesterol, diabetes, stroke, and coronary artery disease [37, 40]. Another risk factor includes light exposure, particularly to blue light, as this generates free radicals and oxidatively damages the eye [41].

All major risk factors for developing AMD are associated with macular pigment as levels are significantly lower in patients with the disease [42]. Assessing visual acuity during a full eye examination is usually the first step toward diagnosis of AMD, along with retinal and choroidal angiography using green dyes [37].

12.4.2.4 Treatment/Prevention

While there is currently limited success with treating advanced age-related macular degeneration, there are many things that can help to prevent or slow the early progression of the disease.

Lutein and zeaxanthin are yellow-pigmented carotenoids that are found in high concentrations in the macula. In the fovea, they are present in amounts 1000 times higher than in other tissues in the body. These xanthophylls help to protect macular photoreceptors and improve vision [43]. Zeaxanthin absorbs damaging high-energy blue light and protects the macula from free radicals, acting as an antioxidant and subsequently protecting the central vision [43]. Carotenoids are not synthesized by the human body, so they must be obtained from the diet. Good dietary sources of lutein and zeaxanthin include leafy greens, such as kale, spinach, and lettuce, as well as broccoli, corn, peas, carrots, oranges, and eggs. There is currently no recommended dietary allowance for lutein or zeaxanthin; however, research has shown a decreased risk for AMD with intakes of only about 6 mg a day and a greater decrease in risk by consuming 10 mg a day of lutein and 2 mg a day of zeaxanthin [44].

Omega-3 fatty acids, including DHA and EPA, and carotenoids lutein and zeaxanthin have a protective effect on the eye, including anti-inflammatory as well as antioxidant [45]. DHA is found in large amounts in the eye, playing a role in phototransduction, as well as photoreceptor function [46]. Like cell membranes, photoreceptor membranes function optimally when they are fluid and selectively permeable—properties that are highly determined by their fat content. There is no RDA for omega-3 intake, but research has shown stabilization of AMD with supplementation of 120 mg DHA and 180 mg EPA a day in patients with AMD [47]. Good sources of omega-3s include fatty fish, such as salmon, and oils, including vegetable oils.

Zinc, cysteine, and alpha lipoic acid have been shown to prevent the progression of AMD and oxidative damage in the eye by acting as antioxidants, protecting tissues from free radical damage [42]. Cysteine can be obtained from consuming cysteine-rich foods, such as protein-rich foods, including meat, poultry, and eggs, or supplementing with N-acetylcysteine. Alpha lipoic acid also plays a role in regenerating other antioxidants, including glutathione, vitamin C, and vitamin E. Taurine is a cysteine-derived antioxidant that is found in high concentrations in the macula [42]. Taurine deficiency leads to retinal photoreceptor degeneration and impaired visual acuity and can be supplemented as 1000 mg twice a day [42].

12.4.3 Skin

12.4.3.1 Biological Structure

The largest of the membrane tissues in the body is the skin barrier which, when intact, provides primary protection from pathogens and undesirables from entering the body. When the skin barrier becomes compromised and loses its integrity, a variety of insults can appear.

12.4.3.2 Insults to Skin Barrier Integrity

Among the most concerning insults to the skin seen in healthcare settings are infection, skin cancers, allergies/sensitivities, and autoimmune diseases. For infections, underlying the vulnerability to protract these infectious insults can be an injury-wound opening access to the inner body. With skin cancers, allergies/sensitivities, and autoimmune conditions, the microenvironment terrain becomes the challenge to assess and know how to treat with considerations of potential antigenic dietary intake, environmental exposures, inflammation, pathogenic triggers of subclinical chronic infections, insufficient or deficient nutritional status, emotional and biological stresses, and genomic propensities.

- Wounds/wound chronic infection/post-op surgical wounds
- Skin cancers
  - *Basal cell carcinoma*
  - *Squamous cell carcinoma*
  - *Melanoma*
- Atopic dermatitis/Eczema
- Psoriasis
- Cracked lesions on or around lips, mouth
- Dermatitis Herpetiforme (extremities and/or truncal)
- Acne/Cystic acne
- Blistering diseases
- Pemphigus vulgaris
- Pemphigus
- Vitiligo

12.4.3.3 Evaluation/Assessment

Inflammation is a common denominator with the above skin conditions. The primary mechanism of healthy control of inflammation is from a balance of fatty acids, especially the omega-6 and omega-3 essential fatty acids and their metabolites that form the prostaglandins PG1, PG2 and PG3, and phospholipids. Obtaining an RBC fatty acid analysis is important to assess the fatty acid composition in order to develop a targeted intervention of food oils and lifestyle choices.

Phytonutrient phenol foods provide anti-inflammatory support to the role of the prostaglandins in inflammation control found in the rainbow of color in fruits and vegetables. The co-nutrients of minerals and vitamins are required for the above control systems to heal and keep inflammation at a healthy maintenance level.

12.4.3.4 Initial Biomarkers for Assessment of Skin Health Status

- Nutrition physical exam of skin and signs of nutritional deficits (face, tongue, skin)
- Skin scraping/biopsy pathology
- Blood
- RBC fatty acid analysis
- Lipid panel (TC, LDL, HDL, TG)
- hsCRP
- Sed rate
- IGG total
- IGE total
- Vitamin D25OH
- Vitamin A retinol
- DHEA-s (AM)
- Tissue transglutaminase IgG, IgA, IgM
- Celiac panel
- Dietary and supplement history
- Medication history

12.4.3.5 Treatment

- Vitamin C
- Biotin
- Fats and oils indicated from individual assessment
- Linoleic acid
- Gamma linolenic acid
- Arachidonic acid
- Saturated fats
- Short-chain fatty acids (SCFA)
- Medium-chain fatty acids (MCT)
- CoQ10
- Vitamin E, full spectrum tocopherols/tocotrienols
- Vitamin D3 (dose per blood test vitamin D25OH/VDR genomic)
- Vitamin A retinyl palmitate (if indicated by testing *vitamin A retinol*)
- Protein
- Amino acids
- Collagen
- Carnosine
- Honey, medical
- Aloe vera

Avoid: trans fats, acrylamide, rancid oils, hydrogenated fats, heat processed vegetable oils, high oleic-vegetable oils, antibiotics, and hormone - containing animal fats.

12.4.4 Brain

12.4.4.1 Biological Structure

The brain is composed of mostly fat, about 60%. Brain cells, otherwise known as neurons, rely entirely on the function of their membrane to serve their purpose of transmitting electrical signals. In order to communicate with one another, neurons generate an influx and/or outflux of specific ions across their membrane to produce an electrical signal to send to a neighboring neuron.

The key to proper function of the brain comes down to the integrity of the blood–brain barrier (BBB), as well as the integrity of axons, neurons, and mitochondrial membranes. The blood–brain barrier has the important function of letting nutrients and certain small molecules into the brain tissue while allowing waste to be eliminated. In addition, the com-

position of the cerebral spinal fluid (CSF) is important to consider along with its relationship with the glymphatic circulatory system (GCS) function of bathing the brain tissue with CSF four times daily. The glymphatic circulatory system has been more recently understood as separate from the body's lymphatic system (Fig. 12.3).

12.4.4.2 Pathophysiology

The BBB can be damaged during concussions and other conditions and is also susceptible to damage from antibodies. If the BBB is disrupted, there can be an increase in autoimmunity to brain tissue, neural inflammation, and oxidative stress to cell and mitochondrial membranes.

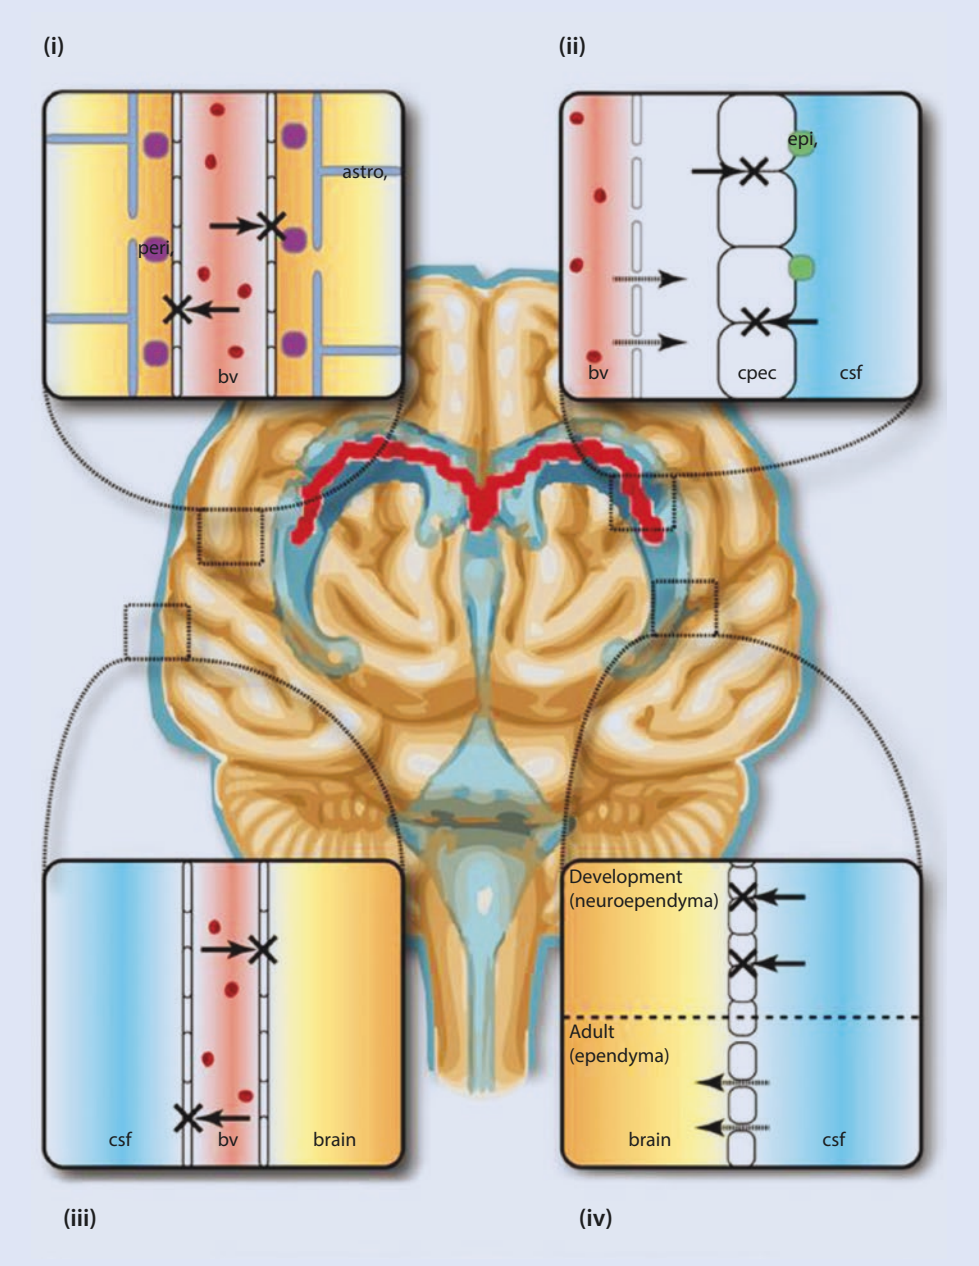

Fig. 12.3 Blood–brain barrier. Protective barriers of the brain. The collective term "blood–brain barrier" is used to describe four main interfaces between the central nervous system and the periphery. (i) The blood–brain barrier proper formed by tight junctions between the endothelial cells of the cerebral vasculature. It is thought that pericytes (peri.) are sufficient to induce some barrier characteristics in endothelial cells, while astrocytes (astro.) are able to maintain the integrity of the blood–brain barrier postnatally. (ii) The blood–CSF barrier formed by tight junctions between epithelial cells of the choroid plexus epithelial cells (note the plexus vasculature is fenestrated). Resident epiplexus (epi.) immune cells are present on the CSF surface of the plexus epithelium. (iii) The outer CSF–brain barrier and the level of the pia arachnoid, formed by tight junctions between endothelial cells of the arachnoid vessels. (iv) The inner CSF–brain barrier, present only in early development, formed by strap junctions between the neuroependymal cells lining the ventricular surfaces. In the adult, this barrier is no longer present. Both the blood–brain and CSF–brain barriers extend down the spinal cord. The CSF-filled ventricular system is depicted in blue, while CNS brain tissue is in brown. The lateral ventricular choroid plexuses are shown in red. Abbreviations: astro, astrocyte; bv, blood vessel; cpec, choroid plexus epithelial cell; csf, cerebrospinal fluid; peri, pericytes. (Reprinted from Stolp et al. [79]. With permission from Creative Commons License 3.0: ► https://creativecommons.org/licenses/by/3.0/)

If damage to the membranes of these neurons occurs to any extent, the entire cell will be absolutely compromised in its ability to complete its purpose in electrical signaling. There is a plethora of clinical conditions, many quite severe, which are associated with the degeneration or malfunction in the membranes of brain cells.

Neurodegenerative diseases are characterized by the progressive loss of neuronal structure or function, leading to neuronal dysfunction [16]. Proper neuronal function relies on all components to be present and intact. Amyotrophic lateral sclerosis, Alzheimer's, Parkinson's, and Huntington's diseases can all be traced back to misfolding and aggregation of certain proteins, resulting in the formation and deposition of fibrils, tangles, and plaques [16]. The accumulation of these harmful proteins is coupled by impairment of mitochondrial integrity, mutations in mitochondrial DNA, reduction of ATP synthesis, oxidative damage, and even cell death [16].

Structural concerns regarding brain function can be the vagus nerve, especially if cervical vertebrae (C1–C2 and C3–C7) are misaligned, impacting the brain stem and vagal nerve. The vagus nerve is the largest nerve network in the body impacting multiple systems including immune, gastrointestinal function, and others. Assessing and correcting the structural components is important as well as treating the function.

12.4.4.3 Evaluation/Assessment

BBB antibodies can be measured as antibodies to protein S100B. If this test is positive, the BBB should be treated to restore proper functions. Similar testing should be done for antibodies to zonulin and occludin, indicating a possible breach in small intestine barrier function. Increased permeability of the BBB is synergistically worsened by increased small intestinal permeability for a number of reasons. Excessive permeability in the small intestine can be a sign of leakage of bacterial endotoxin, as well as food allergens, into the brain, leading to more damage to brain tissue.

Patients with any brain-related matter should be initially tested for gluten antibodies with a complete gluten antibody panel. Patients should also be tested for food sensitivities and immune reactions to the foods that they consume.

It would be reasonable to test any patient with a significant neurological disease for antibodies to brain proteins. Assessing the health of the brain can be accomplished in various ways and is indirect. It can be useful to test for antibodies to the BBB as well as to various brain tissues. If antibodies are found, it is important to treat the cause as well as any symptoms. Quantitative MRI can be performed to assess for gross loss of brain tissue, and QEEG and SPECT scans can be done to look at how the different parts of the brain are functioning.

12.4.4.4 Treatment

The brain is 60% fat, so it makes sense that consuming adequate fat intake in the diet helps nourish the cells of the brain. It is also important to restore the BBB in order to prevent brain autoimmunity, brain damage from free radicals, neuroinflammatory molecules, neurotoxins, and electromagnetic fields.

Nutritional support for the BBB includes optimizing fatty acids and phospholipid dietary and supplemental intake, increasing lipid protectors like fat soluble vitamins and CoQ10, and increasing polyphenols found in blueberries, especially wild blueberries, in order to decrease oxidative damage. Resveratrol can be used to regulate MMP9 and protect against OxLDL damage of the BBB. Curcumin, given 400 mg twice a day, should also be used in the Longvida form to inhibit microglial activation and MMP9, as well as to prevent damage to the tight junctions in the blood–brain barrier [48, 49]. R-lipoic acid taken in 150–200 mg doses twice a day can decrease oxidative stress. Sulforaphane inhibits MMP9 and activates NRF2, which can activate the brain's own anti-inflammatory and antioxidant systems [50]. Sulforaphane supplements may not be very effective. Glucoraphanin is the stored form of sulforaphane in cruciferous vegetables. In order to yield usable sulforaphane, glucoraphanin requires the enzyme myrosinase for it to be converted into sulforaphane. Cooking cruciferous vegetables destroys the myrosinase enzyme, thus very little sulforaphane can be obtained from steamed or fried cruciferous vegetables. It is important when eating raw cruciferous vegetables to have a healthy gut microbiome in order to enable some myrosinase activity. The best sources of glucoraphanin include broccoli sprouts and raw broccoli.

An important goal for supporting the brain should be to improve the structure and function of mitochondria and neuronal membranes. Omega-3 fatty acids with a higher percentage of DHA to EPA, and CoQ10 should be used, as well as providing a substrate for neuronal membrane phospholipids phosphotidylcholine (PC), phosphatidylethanolamine (PE), phosphotidylinositol (PI) and phosphatidylserine (PS). These phospholipid nutrients may also play a role in preventing synaptic degradation and reducing excitotoxic damage. PE, PI and PS are anionic phospholipids in the inner leaflet of the plasma membrane of neural tissues. They are made from phosphatidylcholine (PC) and phosphatidylethanolamine in the endoplasmic reticulum in the brain. DHA and PC can promote phosphatidylserine synthesis. Adequate doses of DHA may be in the range of 2–4 g/day, and doses of PC with PE may be in the range of 1–2 g/day [51]. PS can also be taken directly to improve neuronal membranes. After a head injury, PS doses of 300–600 mg twice a day may be used [51]. When used in the absence of a brain injury, lower doses, such as 100–200 mg twice a day, may be used [51]. The patient should also be encouraged to consume dietary sources of choline, which include egg yolks, poultry, collard greens, Brussels sprouts, broccoli, Swiss chard, cauliflower, and asparagus.

When considering maintenance or improvement in neuroplasticity, one must consider increasing the levels of various trophic factors, such as nerve growth factor, neurotrophin, and brain-derived neurotrophic factor (BDNF). Increasing

levels of BDNF may lead to axonal and dendritic sprouting, nerve stem cell differentiation, and may enhance synaptogenesis. Aerobic exercise done in the training heart rate zone (220-age) 70–80% for 30–45 minutes can increase BDNF as well as protect loss of genetic telomere length [52]. Aerobic exercise can also activate NRF2 gene responses [52]. These gene responses can decrease brain inflammation and oxidative stress, which can improve neuronal and mitochondrial membranes.

Stimulation of neural stem cells and synaptogenesis in the brain, especially in the hippocampus, may be encouraged by the use of exercise and certain supplements [53]. These include melatonin 1.5–2 mg taken at night [54, 55], adequate vitamin D dosing to achieve levels of 50–70 ng/mL [56, 57], which would usually be about 5000 IU, and low dose lithium of 10–20 mg [58]. Low dose lithium aids repair of neurons as well as induces neurogenesis of hippocampal neurons and may lower toxicity of amyloid protein [58]. EGCG green tea extract is also beneficial, either by drinking green tea or by taking 200–400 mg/day [59].

Other nutritional interventions to increase BDNF include consuming blueberries with high polyphenol content. Wild blueberries contain the most of these beneficial nutrients. Encouraging patients to make smoothies with frozen wild blueberries is the most practical way to ensure patients are consuming polyphenols. High percent cacao and zinc may also promote BDNF, along with adequate sleep [60].

Taurine is an amino acid that can improve brain structure through a number of mechanisms. It can protect the brain against osmotic changes, has a neurotrophic effect, can activate nerve stem cells, and can enhance neurite (axon or dendrite) growth. Taurine can be safely dosed at 1000 mg twice a day.

Enhancing brain structure can also involve eliminating certain components from the diet. If there is a head injury, the patient should be taken off of gluten and all dairy products, because of cross-reactivity between these foods and neural tissue with subsequent autoimmune or inflammatory reactions in the brain. These reactions may be mediated by TH1, TH17, or microglial cells in the brain. Gliadin from gluten can cross-react with asialoganglioside GM1, myelin basic protein, synapsins, and cerebellar tissue. Milk butyrophilin can cross-react with cerebellar tissue and dairy casein can cross-react with synuclein and oligodendrocytes [61, 62].

Other dietary changes recommended after a RBC fatty acid analysis or fats and oils dietary survey are the intake of beneficial fat-rich foods and supplements when indicated for the individual.

12.4.5 Barriers

12.4.5.1 Biological Structure

The lining of the small intestine is a major barrier tissue whose function is directly supported by the integrity of its structure. The gastrointestinal mucosa forms a barrier between the body and the lumen of the intestines. The role of this barrier is to selectively allow the passage of nutrients and other small molecules across the epithelium of the intestine, while blocking larger, harmful molecules. Disruptions to this barrier can lead to possible autoimmune disease, food allergies, mood disorders, and other conditions.

The alimentary canal consists of the oral cavity, esophagus, stomach, and intestines and is lined with sheets of epithelial cells, forming the intestinal mucosa. The epithelial cells are held together by tight junctions, sealing off spaces between adjacent cells, forming an enclosed barrier between the lumen of the intestine and the surrounding tissues [63]. The epithelium is the innermost layer of the gastrointestinal tract and is responsible for most of the digestion, absorption, and secretion within the GI tract [64]. Maintaining proper integrity of the intestines comes down to the tight junctions holding the epithelial cells together while also regulating the permeability of water, ions, and nutrients.

Tight junctions consist of protein complexes located at the apical ends of the lateral membranes of the intestinal epithelial cells, forming the selectively permeable seal of the GI tract [63]. There are four specific complexes, including the occludin, claudin, junctional adhesion molecule, and tricellulin [63]. These proteins interact with the actin in the cytoskeleton, allowing a barrier to form [63].

12.4.5.2 Pathophysiology

Disruption to the intestinal epithelial barrier, namely increased permeability, leads to overall gut dysfunction and subsequent GI-related diseases, including irritable bowel syndrome, celiac disease, and leaky gut syndrome [12]. Factors that affect gut permeability include infection, inflammation, immune dysfunction, environmental toxins, medications, and the composition of the gut microbiota [12, 63]. Lipid and zinc deficiencies have also been shown to disrupt tight junctions, alter membrane permeability, and cause intestinal ulcers [12].

12.4.5.3 Evaluation/Assessment

There are many factors that provide some predictability for intestinal permeability, including the use of NSAIDs, bacterial infections, chronic stress, and hypochlorhydria, with an increased likelihood in those with IBS, type 1 diabetes, migraines, celiac disease, and food allergies [65]. Taking cyclooxygenase inhibitors and being deficient in essential fatty acids can also contribute to intestinal permeability [66].

If a patient displays any of these predictability factors, further lab tests can determine the presence of increased intestinal permeability. The lactulose/mannitol test consists of the patient drinking a specific amount of the disaccharide, lactulose, and the monosaccharide, mannitol [67]. The amount of these sugars that are excreted in the urine indicates how well each of these has been absorbed and therefore the degree of permeability in the intestine [12]. Disaccharides are absorbed through the paracellular junction complex within the intestine, indicating the permeability of larger molecules. Increased excretion of lactulose indicates

increased absorption of larger sugars and therefore an increased permeability to molecules that are normally impermeable in the intestine [67].

12.4.5.4 Prevention/Treatment

While damage to the intestinal mucosa can be treated, it is beneficial to prevent disruption in the first place. The probiotic species *Bifidobacterium longum* has been shown to prevent damage to intestinal cells as well as increase the production of tight junction cell proteins, improving intestinal integrity [68]. It has also been shown to successfully treat increased permeability in patients with Crohn's disease and ulcerative colitis [68]. Antioxidants have also been shown to help prevent oxidative damage to the intestine. These include vitamin C, vitamin E, beta-carotene, grape seed extract, milk thistle, and quercetin [69]. Foods that can damage the gut include gluten, dairy, and sugar. Even in non-celiacs, gluten consumption may damage zonulin production, which is a protein that is crucial in tight junctions, increasing permeability to unwanted molecules [70]. Dairy can be inflammatory for a lot of people, so it is best to avoid it when trying to prevent damage to the gut. Too much sugar in the diet feeds the bad bacteria in the gut, causing an overgrowth of bacteria and degradation of gut permeability.

Nutrients that can provide some treatment to the intestine once it is compromised include L-glutamine, which is the primary amino acid source for intestinal cells and regulates intercellular junction integrity, and N-acetylglucosamine (NAG), which is a substrate for the glycosaminoglycans that are normally broken down in a leaky gut. A leaky gut diet should consist of bone broth, steamed vegetables, fermented foods, and healthy fats. Bone broth contains NAG, as well as collagen and glutamine, which are both elements that make up the gut, while steamed vegetables and healthy fats help provide essential nutrients, like L-glutamine, that keep the gut working properly. Fermented foods contain necessary probiotics, which keeps the microbiota in the gut healthy.

Preventing disease in the gastrointestinal tract boils down to the proper maintenance and regulation of the tight junctions that hold everything together. This is a clear example of how optimal function relies on proper, healthy structure.

12.5 Part V: Musculoskeletal Structure and Influences

12.5.1 Introduction

The musculoskeletal system, which is composed of bones, muscles, tendons, joints, and all other connective tissues, is responsible for providing structure and support in addition to functional movement of the body. Though aging has an inevitable effect on musculoskeletal health and function, there are several strategies that can be used to combat this degeneration. Consuming a balanced diet and maintaining a regular exercise routine can aid in healthy and efficient regeneration of musculoskeletal cells as well as maintain current bone density, joint flexibility, and muscle strength. However, there is a plethora of ways in which the musculoskeletal system can begin to develop structural dysfunction. Some of the most common structural changes in the musculoskeletal system are loss of muscle (sarcopenia), tendon degeneration (tendinosis), degradation of joint structure (osteoarthritis), and decreased bone density (osteopenia and osteoporosis). Of those large areas, all of them are modifiable with nutritional interventions, except for tendinosis.

12.5.1.1 Sarcopenia

Sarcopenia is a loss of muscle tissue and is most associated with aging. Muscle tissue may be replaced with fat and connective tissue. Aging also decreases mitochondrial density in muscle tissue. The loss of muscle structure can lead to injuries, falling, and decreased enjoyment of life and participation in sports and activities. Loss of muscle tissue can be related to a number of contributing factors, including hormones, inflammation, nutrition, toxins, and lack of exercise stimulus. The decline of key hormones, such as testosterone, growth hormone, and DHEA, can increase the rate of sarcopenia as well as ongoing systemic inflammation. Resistance training of large muscle groups (biceps, triceps, chest, upper back, thighs, and abdominal wall) to fatigue with sets of 8–12 repetitions should be done two to three times a week. Also, consuming 25–30 g of protein containing at least 2.5 g of leucine (a branched chain amino acid) can augment muscle building from resistance training and can slow age-related sarcopenia. Supplementing with 20 mg of PQQ one to two times per day can increase mitochondrial biogenesis so as to improve energy production from muscle [35]. It is also important for an individual to consume high quality protein on a daily basis of approximately 1 g per kilogram of lean body mass. Muscle content can be monitored with body composition equipment. One of the simplest ways is with a BIA device in which non-fat mass is evaluated (► Chap. 22).

12.5.1.2 Osteoarthritis

Osteoarthritis (OA) is the loss of chondrocytes and matrix from a joint leading to joint space narrowing, sclerosis, and deposits of calcium (osteophytes). Osteoarthritis can be isolated to one joint or be found in multiple weight-bearing joints of the body, including the knee, hips, and spine. Factors that contribute include inflammation, obesity, trauma, infection, lack of adequate precursor nutrients, and possible food allergies. Although the most common approach is to simply work on inflammation with an NSAID, this is an oversimplified and ineffective approach to OA of a joint. As it turns out, the pathophysiology of OA is more complex than simply an excess of prostaglandins. The following processes appear to be involved: inflammation (an extensive set of inflammatory biochemical pathways), lack of adequate precursor nutrients, enzyme breakdown of the joint, and dysfunctional synovial fluid.

12.5.2 Evaluation/Assessment

Evaluation of osteoarthritis is done using a combination of physical examination, since OA joints show warmth, swelling, deformity, or restricted range of motion, as well as imaging studies. X-rays are an excellent, low cost method and may reveal more details than an MRI. However, MRI would be important when evaluating details about labral cartilage or meniscus cartilage.

12.5.3 Prevention/Treatment

Any osteoarthritis intervention can take 8 weeks or more to show a decrease in pain and an improvement in function. For basic nutritional intervention, consuming sulfur-containing vegetables, such as from the cruciferous and onion families, on a daily basis is suggested. Providing sulfur to the chondrocytes in the joint can supply a building block for the joint matrix. It is reasonable to do a trial off of nightshade plants, such as tomatoes, potatoes, peppers, and eggplants, for about 1 month to determine if pain decreases or if function significantly improves. If the pain does improve on this diet, the patient should be kept off of nightshades long term.

There may be an effect from food sensitivities and food allergies. This would be related to an immune complex mediated inflammatory process. In a patient with OA in more than one joint or in a person with hand OA or rapidly progressive hip or knee OA, it is important to try an elimination diet. It is also important to do a food allergy test as well as gluten antibody test. The individual should be taken off of all highly reactive foods for about 8 weeks to see if this decreases pain and improves function.

It is noteworthy that weight loss in overweight or obese people can improve OA by more than simply mechanical factors. As it turns out, obesity can lead to dyslipidemia and oxidized LDL, which can trigger inflammatory pathways in the joints. There is also an alteration in adipokines, which can lead to joint degradation. Any successful approach to weight loss and achieving closer to ideal body weight can help OA of various joints.

12.5.3.1 Omega-3 Fatty Acids

Omega-3 fatty acids can often improve OA by decreasing inflammation. Omega-3 fatty acids can suppress key inflammatory mediators including IL1, TNF-alpha, PGE-2, 5-lox, and cox 2 [71]. They can also inhibit certain metalloproteinases that break down joints, including MMP-3 and 13, as well as aggrecanase. Doses of 3–4 g in two divided doses should be given [71]. Consideration should be given to digestive enzyme (lipase) support in the individual that has difficulty with fat digestion.

12.5.3.2 Vitamin C

A key vitamin for joint health is vitamin C. Adequate levels are necessary for collagen and proteoglycan synthesis as well as stabilization of the collagen fibril. Vitamin C should be dosed two to three times per day at doses of 250–500 mg [72].

12.5.3.3 Strontium

Strontium is a nutrient that may be used to increase OPG and IGF-1 and should be thought of in any individual with both OA and osteoporosis. The dose would be 680 mg/day.

12.5.3.4 Glucosamine Sulfate

Stabilized glucosamine sulfate is an essential supplement that should be used in any case of OA. It functions as a building block in the synthesis of structural cartilage matrix substrates, such as glycoproteins, glycolipids, GAGs, hyaluronate, and proteoglycans, and is required to manufacture joint lubricants and protective agents such as mucin and mucus secretions [73]. Glucosamine sulfate has been found to inhibit NF-kB and PGE2 and thus can have anti-inflammatory effects [74]. Crystalline stabilized glucosamine sulfate has been shown to inhibit IL-1beta-induced gene expression of matrix degradation factors MMP-3 (stromelysin-1) and ADAMTS5 (aggrecanase 2), thus having an effect on decreasing enzyme-mediated chondrocyte degradation [75]. Although glucosamine is not generally found in the human diet, it is made from the exoskeletons of shrimp, crabs, and lobsters for use in medical applications. It is also available in a vegan form that is made from corn. The clinician should recommend the sulfate form instead of the HCL form, as well as to make sure that the product is stabilized. It should be dosed one time per day at 1500 mg, unless there is more than one large joint involved, in which case it can be dosed 1500 mg twice a day [76, 77].

12.5.3.5 Osteoporosis and Osteopenia

Osteopenia is defined as less than 2.5 standard deviations below normal of bone density and osteoporosis is defined as greater than −2.5 standard deviations of decreased bone density. This condition can lead to compression fractures of the spine as well as fracture of the hip and forearm. Of interest is that the bone structure is an area that may store metal toxins and certain metals, including lead and cadmium, which may be released during periods of bone loss, such as in menopause and andropause. Conventional treatment programs will use only bisphosphonates; however, these drugs can lead to dysfunctional bones as well as side effects affecting the jawbone. Consideration of the use of dietary supplementation with a series of menaquinones (MK) (vitamin K2) in the form of MK4 and MK7 that promote healthy bone metabolsim.

12.5.4 Pathophysiology

There are many contributing factors related to loss of bone density, including declining hormone levels (estradiol and testosterone), inflammation (including an inflammatory diet), lack of adequate minerals and vitamins, malabsorption of nutrients, such as vitamin A and D, and inadequate loading of bones with exercise.

12.5.5 Evaluation/Assessment

The most appropriate assessment tools are DEXA scans, which will yield the T scores and urinary measures of bone turnover, such as DPD and CTX. Other useful measures are the serum vitamin D25OH test as well as calcium, RBC magnesium, vitamin D 1,25OH, PTH, calcitonin, osteocalcin, estradiol, and testosterone levels.

12.5.6 Treatment/Prevention

Therapeutic dietary measures can include using an anti-inflammatory diet, a more alkaline diet and a diet rich in certain minerals such as calcium, magnesium, vitamin C, and vitamin K. Food sources of calcium appear safer than supplements in regard to improving bone density without raising serum calcium too much (a risk for coronary arteries). One should have at least 500–1000 mg of food-based calcium. The most reasonable source would be dairy unless the individual is sensitive to dairy, in which case other calcium-rich foods can be eaten, such as collard and kale greens, broccoli, sardines with bones, or almonds. If supplements are used, calcium hydroxyapatite appears to have more efficacy than calcium alone in improving bone density. Vitamin D25OH serum levels should be measured and should be brought well above the minimum level. When treating with vitamin D3, an individual's vitamin A status should be assessed with a blood vitamin A retinol test. If depleted or low, vitamin A supplementation should be considered. It is not unreasonable in a patient with osteoporosis to obtain a whole genetic panel of tests as variations in vitamins A (related to the gene BCMO1) and D (related to the gene VDR) metabolism do occur.

Weight-bearing exercise should always augment any dietary approach. Every individual should be doing a walking program as well as resistance training to load the biceps and triceps.

Strong consideration should be given to assessment of estradiol and testosterone. Bio-identical hormone replacement in any woman or man with osteoporosis should be seriously considered.

12.6 Conclusion

Consideration of structural integrity is as important as assessment of function, from cell membranes all of the way up to the structure of skin, eyes, brain, muscles and joints. Improvement of structural integrity is lengthy, and the patient must be educated that it will take time to replace or improve the affected structure to a more healthy status.

13.1 Introduction

Human exposure to exogenous toxin sources (xenobiotics) has increased dramatically over the last few decades as a result of industrialization and globalization. This results in exposures that may be greater, more frequent, and qualitatively different, especially with regard to exposure to new-to-nature substances, compared with exposures that have typified the greater part of our species' evolution prior to the Industrial Revolution.

More than 100 million substances (organic and inorganic chemicals) have been added to the Chemical Abstracts Service (CAS) registry system since its inception in 1965. About 75% of those were added in the last decade, exemplifying the exponential increase in registrations [1]. While the number of chemicals manufactured in high volumes and released into the environment represents a minor fraction of these, it is estimated that there are between 100,000 and 200,000 industrial chemicals in common circulation [2]. The toxicology of the vast majority of these isolated chemicals is either unknown or poorly understood. Even less is known about the effects of complex mixtures of compounds to which humans in industrial societies are routinely exposed.

By definition, *xenobiotics* are substances that are foreign to an organism, the term stemming from the Greek word *xenos* meaning foreigner and *bios*, life. In relation to human health, the term xenobiotic is typically used to refer to artificial substances, which did not exist in nature before their synthesis by humans (e.g. polychlorinated biphenyls, dioxins, pesticides). Alternatively, the term may be used to describe other exogenous toxin sources that are present in much higher concentrations than might be expected naturally (e.g. following consumption of cadmium or mercury-contaminated fish) or ones that would not be expected to be found within a human (e.g. bacterial toxins, mycotoxins).

Exposures are typically regarded as being either acute or chronic. In the case of the former, the toxicity usually manifests after a single, major exposure, and symptoms of toxicity in one or more organs (e.g. liver, kidney, brain, nervous system) are usually evident clinically within a short period (<24 h) following exposure. An example of an acute exposure includes an overdose of non-steroidal anti-inflammatory drugs (NSAIDs) associated with attempted suicide. Chronic toxicity, by contrast, is the result of repeated, lower-dose exposures over longer periods of time. Again, using NSAIDs as an example, long-term usage of this category of drugs can result in long-term damage to the liver [3] and gastrointestinal tract [4], especially the small intestine [5].

Exposure to some xenobiotics may lead concurrently to beneficial effects and adverse effects (e.g. pharmaceuticals). Exposure to xenobiotics may also yield no evident adverse or beneficial effect, owing to a low (i.e. sub-acute) exposure concentration or insufficient duration or frequency of exposure. Adverse effects, such as carcinogenicity, may arise from either acute or chronic exposure and may be delayed, taking years or decades to manifest clinically. Other categories of delayed adverse effect include mutagenicity (potential to cause mutations, as measured, for example, by the Ames test) [6], genotoxicity (potential to cause damage to a cell's DNA or RNA), reprotoxicity (potential to cause adverse effects on sexual function and fertility in males and females, developmental toxicity in the offspring, and effects through or via lactation) and teratogenicity (potential to cause birth defects, typically evaluated in laboratory animals).

The Globally Harmonised System of classification and labelling of chemicals (GHS) (revision 6, 2015) identifies 10 categories of health hazard, namely, acute toxicity, skin corrosion/irritation, serious eye damage/eye irritation, respiratory or skin sensitization, germ cell mutagenicity, carcinogenicity, toxic to reproduction (reprotoxicity), specific target organ toxicity/single exposure, specific target organ toxicity/repeated exposure, and aspiration hazard [7].

Organs and body systems that have specific sensitivities to xenobiotics include the liver, kidney, nervous system/brain, mitochondria, endocrine system, immune system, eyes, and skin. Substances that adversely affect one particular system are referred to accordingly, for example, hepatotoxins (liver), nephrotoxins (kidney), neurotoxins (nerves/brain), mitochondrial toxins, endocrine disruptors, immunotoxins, etc.

Xenobiotic exposure in a given individual may exceed the body's innate biotransformation capacities and contribute to a wide range of different pathologies. Some xenobiotics may affect quality of life, increase the risk of cancer, or impact reproductive potential. While the human body has been gifted with a multitude of different mechanisms and pathways to reduce body burdens of xenobiotics, these have evolved to cater for both the types and exposures of xenobiotic substances associated with the majority of our evolutionary history. Mammals such as humans are less likely to be able to adapt quickly to synthetic xenobiotics as compared with natural ones to which humans have been exposed during the majority of our species' evolution. Long generation times coupled with low selection pressure will limit or slow the rate of evolutionary adaptation to xenobiotics. Hence, herbivorous insect 'pests' that are pre-adapted to a multitude of host plant secondary metabolites (phytochemicals) have the capacity to rapidly develop *insecticide resistance*, a process aided by high selection pressure, rapid generational turnover rate, and prior adaptation of an array of detoxification enzymes [8]. Honeybees, by comparison, that have not needed to adapt to a high phytochemical load, have a much lesser array of protein coding genes, thus creating a marked reduction in the diversity of cytochrome P450 enzymes, glutathione-S-transferases (GSTs), and carboxyl/cholinesterases (CCEs) compared with herbivorous insects. This, in turn, likely accounts for the honeybee's extreme sensitivity to insecticides [9].

In human evolutionary terms, the time scale during which most adaptations evolved represents a period of some tens of thousands of years, excluding the most recent 250 years or so since the Industrial Revolution. The past 70 years has seen the rapid development of industries reliant on organic chemistry (e.g. industrial chemicals, food tech-

nology, plastics, agrochemicals, pharmaceuticals, personal hygiene, cosmetics) and biotechnology (e.g. nanomaterials, vaccines) that now represent important sources of xenobiotic exposure of humans. In addition, the growth, intensification and globalization of large-scale industry, continued reliance on fossil fuels as the primary energy source, increased human dependence on technology and the continuing expansion of polluting transportation systems (road, sea, and air) are associated with significantly increased indoor and outdoor pollution burdens compared with those that occurred over the majority of human evolutionary history.

Possible routes of exposure to xenobiotics are shown in ▶ Box 13.1.

Box 13.1 Routes of Exposure to Xenobiotics

Exposure to xenobiotics occurs via one or more of the following routes:

1. Prenatal [10]: Relevant for xenobiotics capable of placental barrier (e.g. tobacco smoke, mercury, lead, SSRI drugs)
2. Oral: Exposure via breast milk, food, water, beverages, drugs, supplements
3. Inhalation: Relating to both outdoor and indoor pollution
4. Dermal: Especially in relation to cosmetics, toiletries, washing water, medications exposed via the skin, eyes, vaginal, and other mucous membranes
5. Intramuscular: Vaccines and their associated adjuvants may represent important xenobiotic exposure that bypasses both the dermal and gastrointestinal barriers.

13.2 Biotransformation

A healthy human body, uncompromised by polymorphisms affecting critical enzymatic biotransformation (detoxification) pathways, is highly adapted to handling a diverse range of xenobiotic substances below dosage or exposure thresholds that might yield adverse effects. In fact, the body is gifted with an array of xenobiotic-sensing receptors, such as the pregnane X receptor (PXR) that has evolved to regulate genes involved in the metabolism and transport of xenobiotics absorbed from food or the environment and protect the body from their harmful effects [11].

The biotransformation process essentially involves two main phases, referred to as phase 1 and phase 2, respectively. In the former, non-polar, lipophilic xenobiotics are most commonly enzymatically converted to polar metabolites via a diverse family of cytochrome P450 enzymes (CYP), especially in the liver, and also in the kidney, lung, brain, adrenal gland, and gut. In some cases, the polar metabolites may be more cytotoxic than the original xenobiotic, for example, the biotransformation of the insecticide DDT to the metabolite DDE [12], or in the activation of polyaromatic hydrocarbons and nitrosamines in the diet to form carcinogens [13].

Other phase 1 enzymes include flavin-containing monooxygenase (FMO), hydrolyses, epoxide hydrolyses, aldehyde dehydrogenase, monoamine oxidases, and xanthine oxidase [14]. In general, these phase 1 metabolites become substrates

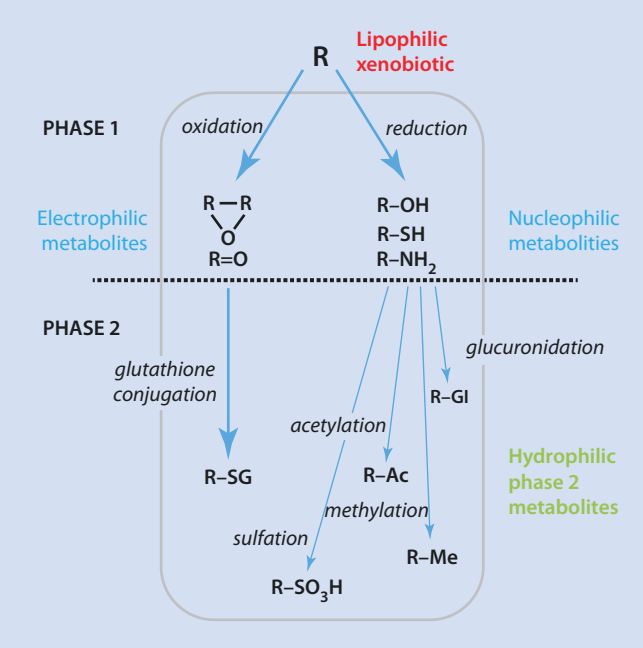

Fig. 13.1 Summary of typical biotransformation of a lipophilic xenobiotic

for phase 2 conjugase enzymes, and following sulfation, amino acid conjugation, glutathione conjugation, glucuronidation, methylation, or acetylation are rendered both less toxic and more water soluble, thereby contributing to urinary or fecal (via the biliary route) excretion (Fig. 13.1) [15]. Chemically modified (more polar) xenobiotics may also be excreted via sweat, as volatile substance by lungs or in human milk [14].

There is increasing recognition of the existence of a complex active transporter (pump) system that is capable of acting on specific xenobiotics (most research having been carried out in relation to pharmaceutical drugs). These are sometimes classified into two discrete, additional biotransformation processes, referred to, respectively, as phase 0 and phase 3 [16, 17].

Both phase 1 and 2 enzymes are highly polymorphic [18]. Accordingly, genetic polymorphisms may contribute to significant inter-individual differences in xenobiotic clearance and responses [19]. A range of other factors also influence inter-individual variations in metabolism of, and response to, xenobiotics, including age, disease status, hormonal changes in the body, ingestion of medications, net exposure to environmental chemicals, and changes in lifestyle, including factors such as cigarette smoking, alcohol consumption, and diet [20, 21].

Given the continued unravelling of the science on biotransformation mechanisms and the growing body of evidence demonstrating the influence of diet and lifestyle on phase 1 and 2 biotransformation, more attention is being placed on dietary and lifestyle modifications that not only reduce the xenobiotic load (i.e. behavioural adaptation to xenobiotics) but also ones that enhance xenobiotic clearance via different and multiple biotransformation pathways.

Dietary composition and individual bioactive constituents can have particularly profound effects on the metabolism of xenobiotics. Animal studies have demonstrated that diets rich in specific saturated and polyunsaturated fats may alter CYP expression, notably of CYP2E1 [22, 23].

Inter-individual responses vary not only according to the potency of the xenobiotic agent(s) and the frequency of cumulative exposure, but also as to the individual's capacity to biotransform and eliminate the agent(s) at a given time. This capacity is dependent on numerous factors, including age, health (including inflammatory) status [24], body size/weight, nutrition, lifestyle, epigenetic background, and polymorphisms affecting biotransformation enzymes.

The clinical phenomenon of *multiple chemical sensitivity* is increasingly well recognized and was usefully defined at a workshop of experts, conducted at the request of the U.S. Environmental Protection Agency (EPA) in 1988, 'as an adverse reaction to ambient doses of toxic chemicals in our air, food, and water at levels which are generally accepted as subtoxic' [25]. The expert workshop concluded that adverse reactions manifest in susceptible individuals depending on a variety of factors, including:

1. The tissue or organ involved
2. The chemical and pharmacologic nature of the toxin
3. The individual susceptibility of the exposed person (genetic makeup, nutritional state, and total load at the time of exposure)
4. The length of time of the exposure
5. The amount and variety of other body stressors (total load) and synergism at the time of reaction
6. The derangement of metabolism that may occur from the initial insults [25]

Intra-individual variation in susceptibility to xenobiotics may also occur temporally, with some patients developing increasing tolerance, or, conversely, increased susceptibility, following continued or repeat exposure to particular xenobiotics.

13.3 Pathophysiology

13.3.1 Mechanisms

Given the huge array of xenobiotics to which humans are now exposed [26] and the general acceptance of their key importance in the pathogenesis of chronic diseases, such as certain types of cancer, it is perhaps surprising that so little, rather than so much, is known about the specific mechanisms by which their effects are mediated. Among the challenges to our improved understanding of the real-world interactions between xenobiotics and humans are the sheer number of xenobiotics to which humans are exposed (and the lack of toxicological knowledge about most of these); the quantitative and qualitative differences in chemical load over time; the challenges facing the study of the effects of exposure to complex mixtures as compared with isolated xenobiotics; [26] the complexity of multigene-environment and epigenetic interactions; the confounding effect of dietary and lifestyle choices; and profound inter-individual variations in susceptibility and tolerance [27].

Dysfunction in homeostatic processes often involve disturbances to the function of interrelated 'super-systems' (e.g. inflammatory, immune, endocrine, neurological) or they may be linked to specific organs or tissues (e.g. liver, kidney, mitochondria, motor neurons).

While there are very large gaps in our knowledge of the mechanisms by which xenobiotics induce adverse effects, three of the most well-researched mechanisms are as follows:

1. *Interference with critical biotransformation steps*. A number of xenobiotics are known to block critical steps in the production of biotransformation enzymes. For example, mercury (e.g. as a contaminant in food) or nitrous oxide (as a gaseous anaesthetic or airborne pollutant) act as potent inhibitors of cobalamin-dependent methionine synthase [28, 29], a critical intermediary in the methionine cycle that is required to synthesize endogenous glutathione, which has the capacity to detoxify both xenobiotics.
2. *Induction of supra-physiological oxidative stress*. Normal metabolic processes, exposure to xenobiotics in our food and environment generate both reactive oxygen species (ROS) and reactive nitrogen species (RNS) [30]. Radical ROS species, characterised by the presence of one or more unpaired electrons, are highly reactive, short-lived molecules, reacting especially with DNA, proteins, and lipids, causing an alteration in their function. While ROS are vital to numerous processes, including signalling cell growth and differentiation, regulating enzyme activity, vasodilation and protecting the host from pathogens and foreign particles, excessive oxidative stress may give rise to DNA, cellular or tissue damage, or to alterations to enzyme function or intracellular signalling pathways. This may, in turn, trigger a wide range of chronic diseases, including heart disease [31] or cancer [32].
3. *Dysregulation of xenobiotic nuclear receptors.* A variety of nuclear receptors, ligand-specific transcription factors, have evolved to sense the presence of toxic metabolites of endogenous metabolism as well as exogenous xenobiotics to which humans are exposed, most notably in the diet. They play a crucial role in biological development, differentiation, metabolic homeostasis, and protection against xenobiotic-induced stresses [33]. Depending on the ligand and the presence of specific cofactors, these nuclear receptors regulate transcription factors that, when functioning properly, control biological functions. However, when expression of these nuclear receptors is dysregulated, they are associated with a wide range of chronic diseases, including asthma, type 2 diabetes, obesity, atherosclerosis, osteoporosis, and cancer [34, 35].

In humans, nuclear receptors can be divided into two main groups according to their ligand-binding specificity [36]:

1. *Orphan receptors*, e.g. constitutive androstane receptor (CAR, NR1I3), pregnane X receptor (PXR, NR1I2), aryl hydrocarbon receptor (AhR), and peroxisome proliferator-activated receptors (PPAR), expressed particularly in the liver and intestines and also in a wide range of other tissues.

   These receptors express a broad range of biotransformation enzymes including CYP1A, CYP1B, CYP2B, CYP3A, CYP2Cs, CYP2A, GSTA1, ALDH1A, MRP3, and MDR1 [32], as well as phase-2 enzymes such as Uridine diphospho-glucuronosyltransferases (UDPGT), glutathione S-transferases (GSTs), and sulfotransferases (SULTs) [37].

   While it has been established that phenobarbital is a major ligand, these receptors have been found to be promiscuous, engaged in 'cross-talk' by stimulating expression of multiple genes, and their function may be promoted (agonist) or repressed (antagonist) by a very broad range of environmental, occupational, and natural products, including many pesticides, pharmaceuticals, dietary chemicals, herbal remedies, and industrial chemicals, typically at micromolar concentrations [36].

   Presently, more than 11,000 ligands have been added to the Orphan Nuclear Receptor Ligand Binding Database (ONRLDB) [► www.onrldb.org], with more than 6500 of these being unique. Orphan receptors for which endogenous ligands are later discovered are referred to as 'adopted orphan' receptors.
2. *Steroid receptors*, e.g. androgen receptor, estrogen receptor (ER), glucocorticoid receptor (GR), and vitamin D receptor (VDR). These receptors are responsive to steroid hormones and exposure to nanomolar concentrations of endocrine-disrupting chemicals (EDCs) such as xenoestrogens which may disrupt normal estrogen signalingsignalling and lead to disease (e.g. estrogen-related cancers) [38].

   Disruption of the function of these receptors and their cross-talk with a broad range of signalling pathways means that xenobiotics affecting steroid receptors may contribute to a daunting range of endocrine-related diseases including metabolic diseases such as cardiovascular, type 2 diabetes and obesity [36], and thyroid diseases [39].

13.3.2 Chronic Diseases Related to Xenobiotic Exposure

Chronic diseases are multifactorial and manifest following highly complex multi-gene/multi-environment interactions, usually over many decades. With limited exceptions (e.g. asbestos- or smoking-related cancers), given the plethora of possible causations, it is often difficult to identify with a high degree of certainty specific causes for particular chronic diseases, given that real-world interactions over multiple decades are likely to give rise to what has been referred to as *symphonic causation* [40].

Given also the vast array of environmental chemicals to which humans are now exposed, it is usually not possible to determine accurately the contribution of environmental chemicals to chronic disease. Notwithstanding this dilemma, exposure to some xenobiotics has been strongly related to specific chronic diseases.

One of the most comprehensive efforts to associate xenobiotic agents with genetic mediators of disease has been through the open-source Comparative Toxicogenomics Database (CTD) [► www.ctdbase.org], an NC State University initiative. The database divides chemicals for which an inferred relationship has been made with human diseases and specific genes into 13 groups and provides an inference score (high score = high inference), with links to the relevant peer-reviewed references. ◘ Table 13.1 provides examples of proven or inferred associations.

The great investment in cancer research over recent decades, the increasing recognition of the importance of environment factors as key triggers in carcinogenesis (as well as in the pathology of other inflammatory and metabolic diseases), along with the emergence of cancer as the leading cause of death in most industrialized, and increasingly in less-industrialized, countries, has stimulated increased interest in establishing scientific consensus over the carcinogenic status of xenobiotics. This role is largely fulfilled by the International Agency for Research on Cancer (IARC), an intergovernmental agency of the World Health Organization (WHO), which publishes comprehensive monographs of the present state of knowledge on carcinogens or potential carcinogens. ◘ Table 13.2 provides a summary of current classifications (including monograph 118) into the five IARC groups.

While the IARC has had a long history of criticism from independent quarters for making 'soft-touch' decisions that avoid negative impacts on the chemical or tobacco industry, it has committed to be more objective [41]. The 2015 decision to include processed meats in Group 1 and the world's top-selling herbicide, glyphosate, in Group 2A, are likely examples of this shift.

While the body of evidence linking a wide range of environmental chemicals to a variety of cancers is indisputable [42], the evidence for an association between environmental chemicals and metabolic diseases like obesity and cancer, as well as processes such as inflammation (refer to ◘ Table 13.1), a key mediator of most, if not all, chronic diseases [43], continues to grow.

Increasing evidence suggests that xenobiotics may interact adversely with the gastro-intestinal (GI) mucosa and microbiome, adversely affecting signalling in the immune, endocrine, and neurological super-system, as well as affecting nutrient assimilation and increasing the risk of a broad range of chronic diseases, including obesity, type 2 diabetes, non-alcoholic fatty liver disease (NAFLD), cardiovascular disease, cancer, and mental diseases [44].

Table 13.1 Chemicals for which associations with human diseases and specific genes have been inferred

CTD chemical category	Top interacting genes	Examples of strongly inferred chemical/human chronic disease relationships [no. genes associated]
Amino acids, peptides, and proteins	CASP3, TNF, GSTP1, IL6, CXCL8, IL1B, MAPK3, ABCB1, MAPK1, HMOX1	Glutathione/prostatic neoplasms [74 genes] Bleomycin/pulmonary fibrosis [35 genes] Cyclosporine/obesity [96]
Biological factors	TNF, IL6, IL1B, NOS2, PTGS2, IFNG, HMOX1, RELA, CXCL8, MAPK3	Lipopolysaccharides/inflammation [79 genes] Mycotoxins/inflammation [15 genes] Aflatoxins/liver neoplasms [2 genes]
Carbohydrates	TNF, NOS2, IL1B, IL6, PTGS2, INS, RELA, IFNG, CASP3, NFKBIA	Lipopolysaccharides/liver cirrhosis [117 genes] Fructose/diabetes mellitus [46 genes] Glucose/carcinoma [59 genes]
Chemical actions and uses	MGEA5, CYP19A1, TNF, IL1B, AR, CASP3, IL6, MAPK1, ACHE, ESR1	Estrogens/carcinoma (hepatocellular) [36 genes] Air pollutants/breast neoplasms [58 genes] Water-pollutant chemicals/breast neoplasms [51 genes] Pesticides/prostatic neoplasms [51 genes] Adjuvants (immunologic)/inflammation [12 genes]
Complex mixtures	TNF, IL6, CXCL8, IL1B, NFE2L2, PTGS2, CYP1A1, HMOX1, NOS2, CAT	Tobacco smoke pollution/stomach neoplasms [102 genes] Smoke/breast neoplasms [101 genes] Particulate matter [lung neoplasms] [79 genes] Chinese herbal drugs/carcinoma (hepatocellular) [55 genes] Vehicle emissions/breast neoplasms [250 genes] Petroleum/prostatic neoplasms [26 genes] Particulate matter/autoimmune diseases [18 genes]
Enzymes and coenzymes	POR, SLC5A6, AKR1B8, CAT, PPARA, CASP3, GAPDH, CYP3A4, NQO1, NQO2	NAD/obesity [8 genes] Thioctic acid/hypertension [41 genes] Leucovorin/heart diseases [2 genes]
Heterocyclic compounds	NOG, AHR, PPARA, CYP1A1, TNF, CASP3, MAPK1, MAPK3, HMOX1, CYP3A4	Tetrachlorodibenzodioxin (TCDD)/liver cirrhosis [763 genes] 2-amino-1-methyl-6-phenylimidazo(4,5-b)pyridine (heterocyclic amine)/carcinoma (multiple) [109+ genes] Nicotine/stomach neoplasms [65 genes]
Hormones, hormone substitutes, and hormone antagonists	ESR1, AR, ESR2, PGR, FSHB, EGF, MAPK1, MAPK3, LHB, TNF	Dihydrotestosterone/prostatic neoplasms [77 genes] Testosterone/breast neoplasms [173 genes] Estradiol/mammary neoplasms [112 genes] Estrogens /carcinoma (hepatocellular) [36 genes]
Inorganic chemicals	APP, CASP3, TNF, HMOX1, CAT, MAPK1, MAPK3, HIF1A, NOG, IL1B	Cadmium/prostatic neoplasms [166 genes] Asbestos/malignant mesothelioma [36 genes] Sodium chloride (dietary)/hypertension [52 genes] Sodium arsenite/ carcinoma (hepatocellular) [147 genes] Arsenic/prostatic neoplasms [168 genes] Hexavalent chromium/lung neoplasms [42 genes]
Lipids	TNF, NOG, IL6, NOS2, IL1B, PTGS2, IFNG, RELA, PPARA, MAPK3	Dietary fats/prostatic neoplasms [222 genes] Arachidonic acid/inflammation [30 genes] Palmitic acid/insulin resistance [18 genes]
Nucleic acids, nucleotides, and nucleosides	CASP3, TP53, TNF, STAR, IL4, IFNA1, CDKN1A, IL6, IL1B, MAPK1	Decitabine (demethylation chemotherapy drug)/carcinoma (hepatocellular) [94 genes] Azathioprine (immunosuppressive drug)/colonic neoplasms [14 genes]
Organic chemicals	NOG, TNF, CASP3, MAPK1, PPARA, MAPK3, CYP1A1, AHR, PTGS2, ACHE	Benzo(a)pyrene/prostatic neoplasms [382 genes] Bisphenol A/prostatic neoplasms [462 genes] Diethylhexyl phthalate/breast neoplasms [112 genes] DDT/carcinoma (hepatocellular) [38 genes] Polychlorinated biphenyls/breast neoplasms [75 genes] Benzene/lung neoplasms [54 genes] Dieldrin Acrylamide/breast neoplasms [35 genes] 1,2,5,6-dibenzanthracene (polyaromatic hydrocarbon)/carcinoma [24 genes] Glyphosate/colonic neoplasms [13 genes]

Table 13.1 (continued)

CTD chemical category	Top interacting genes	Examples of strongly inferred chemical/human chronic disease relationships [no. genes associated]
Polycyclic compounds	AHR, ESR1, CYP1A1, TNF, CASP3, AR, HMOX1, MAPK1, MAPK3, ESR2	Benzo(a)pyrene/prostatic neoplasms [382 genes] Polycyclic hydrocarbons (aromatic)/breast neoplasms [28 genes] Simvastatin/liver cirrhosis [31 genes] Naphthalene/lung neoplasms [34 genes]

Based on data from: Comparative Toxicogenomics Database [CTD] [► www.ctdbase.org]

Table 13.2 International Agency for Research on Cancer (IARC) categorisation of carcinogens and examples

IARC category	Scientific basis of IARC classification	Number of entries (2017)	Examples
Group 1	Carcinogenic to humans	120	Alcoholic beverages, aflatoxins, aristolochic acid, arsenic, asbestos, benzene, benz(a)anthracene, cadmium, benzo(a)pyrene, coal, coal tar, chromium (VI) compounds, diesel exhaust, dioxin, ethanol in alcoholic beverages, lindane, Epstein-Barr virus, Estrogen-progestogen menopausal therapy (combined), Estrogen-progestogen oral contraceptives (combined), ethylene oxide, formaldehyde, *Helicobacter pylori* infection, Hepatitis B and C virus (chronic infection), human papillomavirus (HPV) types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, ionizing radiation, leather dust, untreated mineral oils, naphthylamine, nickel compounds, paints (occupational exposure of painters), polychlorinated biphenyls, outdoor air pollution, processed meat (consumption of), radionuclides, various forms of radium and their decay products, rubber manufacturing industry, salted fish (Chinese style), shale oils, crystalline silica dust, solar radiation, soot, Tamoxifen, tobacco (smoking, second-hand smoke, smokeless, chewing), trichloroethylene, ultraviolet-emitting tanning devices, vinyl chloride, wood dust, X- and Gamma-radiation
Group 2A	Probably carcinogenic to humans	81	Acrylamide, anabolic steroids, adriamycin, wood (and other biomass) fuels, bitumens, Captafol, chlorinated toluenes, chlorozotocin, Cisplatin, creosotes, cyclopentalpyrene, dibenzacridine, dibenzopyrene, dimethylhydrazene, dimethyl sulphate, ethyl carbamate (urethane), ethylene dibromide, emissions from high temperature frying, occupational exposure as hairdresser or barber, glyphosate, inorganic lead compounds, infection by *Plasmodium falciparum* (that causes malaria), mate (hot), Merkel cell polyomavirus, 5-methoxypsoralen, methyl methanesulfonate, N-methyl-N′-nitro-N-nitrosoguanidine (MNNG), ingested nitrates or nitrites (under conditions that result in endogenous nitrosation), nitrogen mustard, 1-nitropyrene, N-nitrosodimethylamine, N-nitrodimethylamine, 2-nitrotoluene, application of non-arsenical insecticides (occupational exposure), petroleum refining, polychlorinated biphenyls (PCBs), red meat (consumption of), shift work involving disruption of circadian rhythms, styrene-7-8-oxide, tetrachloroethylene (perchloroethylene), 1,2,3-trichloropropane, vinyl bromide, vinyl fluoride
Group 2B	Possibly carcinogenic to humans	294	Aflatoxin M1, acetaldehyde, acetamide, para-aminoazobenzene, anthraquinone, benzofuran, benzophenone, benzyl violet 4B, bitumens, occupational exposure to straight-run bitumens and their emissions during road paving, caffeic acid, carbon black, carbon tetrachloride, chloroform, cobalt and cobalt compounds, cobalt metal without tungsten carbide, coconut oil diethanolamine condensate, para-dichlorobenzene, diethanolamine, ethylbenzene, gasoline, human immunodeficiency virus type 2 (infection with), human papillomavirus types 26, 53, 66, 67, 70, 73, 82, lead, magnetic fields (extremely low-frequency), methylmercury compounds, metronidazole, mitoxantrone, naphthalene, nickel (metallic and alloys), nitrobenzene, ochratoxin A, pickled vegetables (traditional in Asia), phenobarbital, styrene, talc-based body powder (perineal use)

(continued)

Table 13.2 (continued)

IARC category	Scientific basis of IARC classification	Number of entries (2017)	Examples
Group 3	Not classifiable as to carcinogenicity in humans	505	Aciclovir, actinomycin D, amaranth, para-aminobenzoic acid, ampicillin, anaesthetics (volatile), arsenobetaine and other organic arsenic compounds that are not metabolized in humans, atrazine, benzoyl peroxide, bisphenol A, diglycidyl ether (Araldite), bisulfites, caffeine, carrageenan (native), chlorinated drinking water, chloroquine, cholesterol, chromium (metallic), coal dust, coumarin, crude oil, cyclamates (sodium cyclamate), diazepam, electric fields (extremely low-frequency), electric fields (static), ethylene, fluorides (inorganic, used in drinking-water), haematite, human papillomavirus genus beta (except types 5 and 8) and genus gamma, lead compounds, organic (NB: Organic lead compounds are metabolized at least in part, to ionic lead both in humans and animals. To the extent that ionic lead, generated from organic lead, is present in the body, it will be expected to exert the toxicities associated with inorganic lead), magnetic fields (static), mineral oils (highly refined), acetaminophen (paracetamol), polyethylene, polypropylene, polystyrene, saccharin and its salts, tea, temazepam, vitamin K substances
Group 4	Probably not carcinogenic to humans	1	Caprolactam

Emerging evidence suggests that xenobiotics may cause significant alteration to the microbiota in the human gut. Antibiotics and other oral pharmaceuticals may create significant short- or long-term changes in GI microbiome stability as well as changes to the relative abundance of particular bacterial taxa. Older patients on long-term prescriptions and polypharmacy may suffer reduced microbiota stability and diversity [45]. A study on the effect of the antibiotic cephalosporin on wild gorillas showed that the drug had a statistically significant tendency to increase *Firmicutes* (Gram positive) and decrease *Bacteroidetes* (Gram negative) colony numbers and species diversity, [46] a pattern that is associated with obesity in humans [47].

Further evidence implicates certain groups of pesticides, persistent organic pollutants (e.g. polychlorinated biphenyls), heavy metals (e.g. cadmium, mercury), food additives, and nanomaterials in further disturbances to the GI microbiota [48].

Xenobiotics, most notably excitotoxins and neurotoxins capable of passing the blood–brain barrier such as those transported by P-glycoprotein, are increasingly implicated in neurological diseases such as Parkinson's disease [49, 50], especially among those who are genetically more susceptible (e.g. organophosphate insecticide-exposed individuals homozygous for the paraoxonase 1 (PON1–55) gene) [51].

Other organs, tissues, and organelles that may be particularly vulnerable to xenobiotics are those directly involved in biotransformation (liver, kidney) [52], excretion (colon, bladder, urethra) [53], and energy production (mitochondria) [54].

13.4 Clinical Considerations

Where xenobiotics are thought to have been a trigger or mediator of a particular disease or condition, an integrative and functional medicine approach necessitates three main areas of investigation prior to the development of a treatment plan:

13.4.1 Assessment of Xenobiotic Exposure, Historically and Presently

This assessment, likely based on patient interview, should take into account known prenatal, childhood, occupational, and other lifetime exposures.

Xenobiotics may be categorized according to the CTD (Table 13.1); given the extreme sensitivity to xenoestrogens, consideration should be given to even very low levels of exposure to xenobiotic hormones or hormone analogues that act as endocrine disrupting chemicals (EDCs) even at nanomolar concentrations, close to the limit of analytical detection.

All five routes of potential exposure (▶ Box 13.1) should be considered, taking into account indoor pollutants (e.g. flame retardants, mycotoxins from moulds), xenobiotics in foods (e.g. preserved meats, polyaromatic hydrocarbons/heterocyclic amines on charred/high temperature cooked foods, food additives, sugar, pesticide contamination), outdoor pollutants, chlorinated/fluoridated drinking water, cosmetics, toiletries, etc.

Risk is determined by both the exposure (including dose and frequency) and an individual's susceptibility, the latter being heavily predicated genetically (Table 13.3).

Table 13.3 Important single nucleotide polymorphisms (SNPs) affecting biotransformation of xenobiotics

Phase	Gene	Gene variant	Risk allele	Example of impact	Reference
Phase 1	CYP1A1*1 (M1)	Msp1T>C	C	Metabolic of estrogens and polyaromatic hydrocarbons into carcinogenic reactive metabolites	Moorthy et al. (2015) [55], Sharma et al. (2014) [56]
	CYP1A1*2 (M2)	Ile462ValA>G	G		
	CYP1A2*1C	3858G>A	A	Metabolic activation of heterocyclic amines (HCAs) and aromatic amines (AAs) (e.g. in high temperature cooked meats)	Wang et al. (2012) [57]
	CYP1A2*1F	164A>C	C	CC (homozygote) individuals are 'slow' metabolizers of caffeine	Cornelis et al. (2006) [58]
	CYP2E1	96-bp insertion	N/a	Bioactivation of N-nitroso compounds derived from processed meats containing nitrite preservatives	Jiang et al. (2013) [59], Cross and Sinha (2014) [60]
Phase 2	COMT	Val158M	A	Slow COMT expression may lead to reduced methylation and increased DNA damage	Tahara et al. (2009) [61]
	MTFHR	C677T	T	Homozygote (and to a lesser extent heterozygote) individuals of each polymorphism have impaired methylation, increased risk of neurotransmitter disturbances and cardiovascular disease, and are slow (~70% reduced) metabolizers of folic acid to bioactive 5'-methyl-tetrahydrofolate	Stover (2011) [62], Alizadeh et al. (2016) [63]
	MTHFR	A1298C	T		
	N-acetyltransferase (NAT)2	Multiple, incl. 590A, 341C, 481T, 803G and 282T	Various	Holders of non-wild type alleles may have various combinations of alleles making them slow acetylators, affecting the metabolism of many drugs	Sabbagh et al. (2011) [64]
	Glutathione S-transferase (GST)M1	Deletion	Null	Deletions of these members of the GST gene (mu and theta 1 positions) superfamily are associated with reduced glutathione conjugation and elevated risk of some cancers	Bolt and Their (2006) [65]
	GSTT1	Deletion	Null		
	Aldehyde dehydrogenase (ALDH2)	rs671 G>A	A	Significantly reduced capacity to convert aldehydes (including from alcohol consumption) to acetate	Way et al. (2017) [66]
	PON1–55	55 L>M	M	MM homozygotes are more susceptible to adverse effects following exposure to organophosphate insecticides; associations with increased risk of Parkinson's disease	O'Leary et al. (2005) [67], Manthripragada et al. (2010) [68]
Phase 1/ Phase 2	SULT2B1	Multiple, including SULT2B1b and SULT2B1a	Various	Key member of the steroid metabolizing sulfotransferase (SULT) gene superfamily; imbalanced metabolism of hydroxysterois hormones and cholesterol	Ji et al. (2007) [69]

In some cases, it may be necessary to determine the presence of specific chemicals using relevant tests, e.g. lipid-soluble chemicals following fat biopsy, water-soluble chemicals via urine or sweat, or neurologically active pesticides using acetylcholinesterase assay.

13.4.2 Assessment of Genetic Susceptibility

An increasing array of genetic tests is commercially available to evaluate specific single nucleotide polymorphisms (SNPs) that increase (or decrease) susceptibility to xenobiotic agents (Table 13.3).

Special consideration should be given to individuals expressing multiple high-impact polymorphisms relating to compromised biotransformation.

13.4.3 Assessment of Diet and Lifestyle

Of key importance are elements of diet and lifestyle that affect exposure to, or enhance, biotransformation of xenobiotics.

Diets including regular consumption of highly processed or ready-made foods, high-temperature cooked foods, and ones low in a diversity of vegetables and fruit generally contain larger amounts of synthetic additives, contaminants or other xenobiotic compounds as well as fewer disease protective compounds. Food and lifestyle diaries are a useful means of gaining information about a patient's habits and potential exposures.

13

13.5 Clinical Strategies

Key strategies may be divided into those that reduce total xenobiotic load.

13.5.1 Reducing or Avoiding Exposure to Xenobiotics

The most important way of modifying risk to environmental toxins is to avoid, or at least reduce, exposure to them. The following section draws on strategies proposed by renowned functional medicine doctor, Mark Hyman, MD [70].

Reduction or avoidance strategies include:

- Avoid processed foods; consume whole foods, home-prepared for freshness and to avoid nutrient loss where possible
- Consume organically certified or guaranteed pesticide-free produce. This is especially important when consuming fatty foods (e.g. dairy produce, vegetable oils, fatty meats) that tend to accumulate pesticides, veterinary drugs, and POPs
- Reduce or eliminate personal care products that contain harmful ingredients (e.g. phthalates, parabens, PEGs, propylene glycol)
- Eliminate or avoid excess exposure to petrochemicals, agrochemicals, and other sources of environmental toxin, for example, garden chemicals, dry cleaning, car exhaust, second-hand smoke
- Reduce or eliminate the use of toxic household cleaners (use low toxicity, environmentally friendly versions, wear gloves to avoid skin contact)
- Avoid unfiltered, municipal tap water. A reverse osmosis or distillation system are the only two systems that remove xenoestrogens, although it is advised to re-mineralize water (to at least pH 7.5) with a suitable mineral source prior to drinking
- HEPA/ULPA filters and ionizers can be helpful in reducing dust, moulds, volatile organic compounds, and other sources of indoor air pollution
- Avoid high-temperature cooking, such as frying and deep frying
- Avoid using PTFE-coated non-stick-treated pans (that may release fluorine gas during high-temperature cooking)
- Do not drink water or drinks from plastic bottles, unless they are guaranteed BPA-free (use glass bottles)
- Avoid storing food in plastic containers, or covering food in plastic wrapping, especially where food contact occurs, unless it is guaranteed to be phthalate-free (use glass or earthenware for food storage)
- Clean and monitor heating systems for release of carbon monoxide
- Include houseplants throughout house (including bedrooms) to help filter the air and increase oxygen concentration
- Air dry-cleaned clothes in well-ventilated space before wearing or storing
- Use solvent-free (water-based) paints if decorating interior spaces
- Avoid inhaling heavy traffic fumes, especially when exercising heavily (e.g. running, cycling). A respirator containing both particulate and carbon filters will reduce the level of harmful exposure, but filters should be changed regularly
- Understand all sources of possible workplace exposure and take action to avoid or minimise. In some cases, it may be helpful to engage the relevant trade union for assistance
- Use a carbon filter on baths or showers (and replace regularly according to manufacturer specifications) or reduce their duration
- Avoid chlorinated swimming pools; preferably, swim in sea water or other natural, open water or use seawater or ozone-treated pools
- Prospective mothers should ensure they have minimized exposure to environmental toxins 6–12 months before planning to get pregnant and should minimise exposure to xenobiotics throughout breastfeeding
- Avoid taking antacids, paracetamol, or other common over-the-counter medications and seek support for natural/non-drug alternatives
- Remove allergens and dust in living areas as much as possible

- Minimize exposure to electromagnetic radiation (EMR) from cellular or cordless phones by ensuring time spent with handset close to head or body is kept to a minimum. Do not carry phones in pockets or close to the body unless turned off. Do not sleep with phone near bedside if left on. Use 'air tubes' or speakers to reduce proximity of phone to head/body when talking. Use radiation protection cases or sleeves on mobile devices
- If working on computer, ensure screens and main computer are at least 30 cm from body. Use separate wired keyboard and low-radiation screen if laptop is main computer
- Do not use cordless telephones as most base stations emit EMR equivalent to transmission mast 250 m from house. Use corded phones for landlines
- Avoid excessive time (more than 1–2 h/day) watching television or using screens and sit more than 3 m away from television when watching
- Avoid use of microwave ovens
- Avoid excessive exposure to sun (avoid burning)
- Avoid any exposure to X-rays other than those regarded medically essential
- Reduce heavy metal exposure (predatory and river fish, some municipal drinking waters, lead paint, thimerosal-containing products, etc.)

13.5.2 Supporting the Body's Detoxification Capacity

There is a large body of research, as well as decades of clinical experience, supporting nutritional approaches to enhancing biotransformation (detoxification) processes in the body [71, 72].

13.5.2.1 Improve Elimination of Toxins

- Try to ensure 1–2 bowel movements a day
- Drink 6–8 glasses of clean drinking water a day
- Sweat regularly (use exercise, steam baths, and/or saunas to encourage sweating)
- Regular physical activity and exercise, yoga, or lymphatic massage can improve lymph flow and assist elimination of toxic metabolites
- Consume adequate soluble and insoluble fibre: approx. 30g/day
- Consume legumes (generally cooked to reduce/eliminate lectins), whole grains (preferably gluten-free), vegetables, fruits, nuts, and seeds
- Consume fermented foods as natural probiotic sources

13.5.2.2 Foods that Support Biotransformation

- Cruciferous vegetables (cabbage, broccoli, collards, kale, Brussels sprouts) containing indole-3-carbinol, sulforaphane, etc., at least 1–2 cups daily
- Garlic cloves (several daily) or garlic (preferably kyolic aged) supplement
- Decaffeinated green tea; preferably morning
- Freshly made vegetable juices, e.g. kale, celery, cilantro, beets, parsley, ginger, and carrot (the latter should be limited because of its high sugar content)
- Herbal detoxification teas, e.g. burdock root, dandelion root, ginger root, liquorice root, sarsaparilla root, cardamom seed, cinnamon (not cassia) bark, etc.
- High-quality, sulfur-containing proteins; eggs, plant protein (not soya) isolates, as well as garlic and onions
- Citrus peels, caraway and dill oil (limonene sources)
- Bioflavonoid/polyphenol-rich berries, grapes, citrus, and other fruits
- Dandelion greens may help in liver detoxification, improve the flow of bile and increase urine flow
- Celery may increase urine flow
- Fresh cilantro may help eliminate 'heavy metals'
- Rosemary, as fresh herb or extract, promotes expression of biotransformation enzyme genes, chelates heavy metals, antioxidant, anti-inflammatory
- Turmeric/curcuminoids (in fresh and dried turmeric and curry powders): exhibit multi-target functions including detoxification, antioxidant, and anti-inflammatory effects
- Chlorophyll in dark green leafy vegetables, wheat grass, etc.

13.5.2.3 Dietary/Food Supplements that May Support Enhanced Biotransformation

- Full-spectrum, high-quality multivitamin and mineral formula including bioavailable nutrient forms
- Buffered vitamin C (with mineral ascorbates): 1000–4000 mg a day in divided doses (to avoid loose stools) in powder, capsule, or tablet forms during periods of increased detoxification. If dosage causes loose stools, lower dose
- Milk thistle (*Silybum marianum*): 200–600 mg silymarin/day
- Rosemary (*Rosmarinus officinalis*) extract: 200–500 mg dry extract/day (standardized to 6–10% rosmarinic acid)
- Turmeric curcuminoids with bioavailability enhancer (e.g. turmeric essential oils, cyclodextrin, piperine): 200–600 mg curcuminoids/day, in divided doses
- Astaxanthin (from *Haematococcus pluvialis*): 5–20 mg/day
- Vitamin B6 (as pyridoxal 5′-phosphate): 10–25 mg/day
- Vitamin B12 (as methylcobalamin): 500–10,000 µg/day
- Folate as (6S)-5-methyltetrahydrofolate (glucosamine salt), calcium methylfolate, or food-form folates [73]: 1500 µg/day
- Omega-3 fatty acids (as EPA and DHA): 2000–5000 mg/day
- Liposomal glutathione: 400–800 mg/day

Additional supplements (for use under medical supervision):

- N-acetylcysteine: 500–1000 mg a day
- Amino acids: taurine 500 mg twice/day, glycine 500 mg twice/day
- Alpha-lipoic acid: 100–600 mg a day
- L-carnitine: 1000–2000 mg a day in divided doses
- Bioflavonoids (citrus, pine bark, grape seed, green tea): 50 mg/day

13.6 Conclusions

There is growing evidence that xenobiotics are playing an increasing role in a wide variety of chronic diseases and multi-morbidities that present the primary burdens on healthcare system [74]. The specific manifestation of disease in a given individual is dependent on extraordinarily complex and generally poorly understood gene-environment interactions, mediated by disrupted nuclear transcription factor trafficking and signalling pathways.

The huge, variable, and unpredictable array of xenobiotics to which individuals are exposed presently, coupled with the genetic and epigenetic variability, make it almost impossible to assess the net effect of xenobiotic load on an individual. This dilemma is compounded further by the absence of adequate toxicological and toxicogenomic data on environmental chemicals, acting both singly or, even more relevant to real-world situations, as mixtures.

Toxicogenomics offers a new lens through which to understand more about the effects of xenobiotic exposure mediated by effects on specific genes and signalling pathways. The clinical practice of integrative and functional medicine is unique in its emphasis on trying to establish causes, triggers, and mediators of chronic disease, often much earlier in the disease cycle than with conventional medical approaches.

Rapidly emerging omics sciences, including nutrigenomics and metabolomics, as well as cost-effective testing of SNPs for gene variants associated with compromised biotransformation, are further able to assist clinicians in their development of personalised protocols for their patients.

Despite these complexities, a number of robust strategies apply to most, if not all, cases: every effort should be made to help patients minimise total xenobiotic exposure and body load, while dietary and lifestyle patterns that promote effective biotransformation and elimination of metabolites should be strongly encouraged.

14.1 Introduction

Detoxification is the process by which the body breaks down and removes substances that are undesirable and have potential for harm. These can be endogenous waste products or such exogenous substances as medications, environmental toxins or any substances that we ingest, inhale or absorb. Detoxification is a natural process of the body carried out continuously by the liver, the kidneys, the skin, and the lungs [1].

"Detox" is a popular topic and there is a lot of disagreement about what it is and how to do it. While many companies sell detoxification products, the claims that these products are essential to cleanse the body are often exaggerated. The body is designed to effectively eliminate toxins in the majority of cases. Using a radical detoxification product and then returning to the same poor dietary and lifestyle habits is like going on an extreme diet for weight loss and then returning to the prior way of eating. The approach of using an aggressive detoxification product is not necessarily effective to help the body function properly and may even result in harm. Better approaches to detoxification are discussed below.

The critical role of detoxification is handled primarily by the liver [2]. Rich blood flow is seen throughout the liver, bathing its columns of orderly arranged cells separated by spaces. As the blood is transported through the spaces between the liver cell units, it is filtered and chemicals, dead cells, drugs, microorganisms, and other debris are removed from the bloodstream. Important in this process, Kupffer cells are specialized macrophages found in the liver sinusoids and make up more than 80% of macrophages found in the entire body. Kupffer cells are especially important for elimination of infectious agents circulating in the blood filtered through the liver, but also important for other debris and toxin degradation [3]. A significant elaborate system of breakdown of the removed debris is handled by several step processes, beginning with the inherited cytochrome P450 enzymes that require important cofactors for function in the form of nutrients such as B vitamins [2]. (Please see ▶ Chap. 13). This critical first phase of the detoxification addresses fat-soluble toxins that are chemically converted into intermediate metabolites that become more water-soluble. The second phase completes the chemical transformation into water-soluble compounds on their way to excretion into bile and subsequently into the gastrointestinal tract for removal from the body. Amino acids, vitamins, and other cofactors are important for this second phase. More in-depth understanding can be gained from ▶ Chap. 13.

The kidney's filtering system is comprised of glomeruli that remove waste products and toxins from the blood with subsequent excretion into the urine [4]. Urinary excretion is one of the primary ways that toxins are eliminated. Kidneys not only eliminate wastes but also maintain levels of water and minerals, produce renin to manage blood pressure, synthesize erythropoietin to make red blood cells, and synthesize the active form of Vitamin D for strong bones and a variety of other functions. We want to do everything we can to keep these important organs healthy.

Encountering a patient immediately following an alcoholic binge, one notes a distinctive odor emanating from the skin; this is the body's way to eliminate alcohol metabolites. We often don't think of the skin as an organ of elimination, but waste products and toxins, such as heavy metals, phthalates, and other environmental toxins do diffuse into the sweat glands for elimination in the sweat [5, 6]. Saunas are often promoted for their detoxification effects due to the benefits of sweating. Vigorous exercise with sweating has similar outcomes.

The lungs are primarily designed to remove carbon dioxide in exhaled breath, but the lungs are also able to filter and remove other waste products [7]. A well-known example is a diabetic patient in ketosis exhaling ketones in the breath, with its characteristic odor. While this is often described as a fruity odor, the actual chemical odor being eliminated is acetone. Other metabolites are also eliminated by the lungs when in abundance, which brings up images of a breathalyzer in the hands of a police officer. However, exhaled breath has the potential to surpass blood and urine for toxicity testing because breath gives unlimited supply, does not require trained medical personnel, is noninvasive, and does not produce potentially infectious waste such as needles.

14.2 Primary Approach – Avoidance

The primary approach to detoxification is avoidance of the exposure when possible. Unfortunately, the majority of populations around the world are exposed to chemicals and foreign substances that were not present until the early twentieth century. Estimates suggest there are almost 100,000 chemicals in current use with only a fraction of them rigorously tested for safety in humans [8]. A further concern is that tested chemicals are evaluated based on a single exposure without interaction with other chemicals, unlike the daily experience where humans are exposed to a chemical soup from personal care products, food contaminants, drugs, pesticides, etc. Since exposure to multiple chemicals occurs daily, the risk of toxicity is actually much higher and taxes the detoxification system. This makes the concept of avoidance even more critical, and patients need to be educated about the potential sources of exposures. The more patients are aware of exposures, the better equipped they will be to reduce them. Ultimately this leads to reduced burden on the normal biological processes [9].

What we now call "organic food" was simply called "food" 100 years ago. People had relatively small plots of land where they usually had a combination of animals and crops. The manure from the animals and other organic waste were composted to provide fertilizer for the garden and field plantings. Currently, the majority of crops are farmed large in monoculture plots using chemical fertilizers, pesticides, herbicides, and fungicides. Monoculture farming and use of chemicals on the land have led to nutrient depletion of the soil [10, 11]. Some crops are "Roundup

Ready," meaning that they are genetically modified to withstand large amounts of herbicide (glyphosate). Besides being a risk for cancer, kidney disease and other health problems, glyphosate can bind with minerals in the soil including copper, iron, magnesium, manganese, nickel cobalt and zinc, making them less available in our food [12]. Roundup is also sprayed on other crops, such as wheat, as a desiccant prior to harvest [13, 14].

It is not only plant food that is modified with chemicals. Animals are factory farmed in crowded warehouses or pens, making them more susceptible to distress and disease [15]. They are fed food containing genetically modified (GMO) corn and soy and are given antibiotics and hormones to hasten weight gain. When cattle are crowded into pens full of urine and feces, is it any surprise that *E.coli,* a fecal-borne bacteria, can end up in the meat [16]? It is not a healthy situation for the animals or those who consume them.

Cattle are intended to eat grass and similar plant materials as they have four stomachs designed to break down the cellulose. Feeding cattle grain is not a healthful alternative. Nor is crowding the animals in pens without exercise options or giving them chemicals and antibiotics to produce rapid weight gain. These procedures produce a marbling appearance in meat that many people desire and create a milder flavor; but these practices do not contribute to animal health and well-being or health benefits for those who consume the meat produced in this manner.

When large amounts of urine and feces are produced in small contained areas by animal factory farming, there is often contamination of nearby groundwater [17]. When cattle, poultry or hogs are rotated on pastures in traditional farming techniques, their wastes fertilize the ground without overwhelming the area. Just as with human detoxification, nature has the means to handle the waste products in small quantities.

Our water supply can be contaminated by other sources of toxins. Herbicides such as Roundup, pesticides, lawn chemicals, factory farm waste, heavy metals, and prescription drugs can all be found in tap water [9]. If the water is from a metropolitan water supply (as opposed to a private well), it may also contain fluoride (a neurotoxin) and will have chlorine or chlorinated by-products that have been used to kill microorganisms. The list of possible contaminants is too long to include here, but the recommendation is to use filtered tap water [9]. Reverse osmosis systems are the most effective at removing these, but other filters are also helpful. Bottled water may be no different than tap water, plus there is the risk of leaching endocrine-disrupting contaminants like bisphenol-A (BPA) from the plastic bottle, especially if exposed to sunlight [18].

Common everyday sources of toxic chemicals are in personal care and cleaning products. We have become obsessed with cleanliness and with killing germs to a degree that is unhealthy. Our bodies are hosts to around 100 trillion microorganisms that live in the gastrointestinal tract and on the skin, and these are necessary for health [19]. Anything that disturbs the balance of these microorganisms can create problems. Therefore, any chemical-containing products, particularly antibacterial-containing products for everyday use, should be discouraged [9].

The Food and Drug Administration does not approve cosmetics or personal care product ingredients but is, by law, charged with regulating these ingredients [20]. For example, the FDA has banned the use of triclosan in soaps, but triclosan may still be found in other products such as toothpaste [21]. Otherwise, unless there is evidence of obvious harm, ingredients are not premarket-approved. Because we apply these products directly to the skin, any toxins contained in them can be absorbed. The European Union has banned more than 1100 chemicals that are allowed in the United States [22]. One way to avoid the most toxic products is to use the Environmental Working Group website (► ewg.org), which lists products and rates them according to ingredients.

Cleaning products are even more likely to contain toxic ingredients when compared to cosmetics and personal care products. Most cleaning products do not list their ingredients on the label, and many consumers are unaware of what their exposure may be. There are green products that do list ingredients and are less toxic, and can be found easily locally. Once again, the Environmental Working Group is a source of information that can guide buying decisions. Another option is to make products from safe ingredients and recipes are found on the internet for this purpose.

Are you aware that the "new car smell," the smell of fresh paint, the smell of new carpet and similar smells include chemical fragrances? These are volatile organic compounds (VOCs) and should be avoided as they can be toxic [23]. Air fresheners, fabric softeners, oven cleaners, flame retardants, and plastic food containers should also be avoided for similar reasons [9]. Unscented products and low VOC products are preferred. If fragrance is desired, essential oils provide a better alternative than artificial fragrances which contain multiple chemicals and phthalates (hormone-disrupting chemicals).

Now that we have discussed the first step, avoidance of toxins, let us look at ways that we can support the detoxification process by care of organs of detoxification and aiding excretion through liver and kidneys.

14.3 Secondary Approach – Caring for Organs of Detoxification

14.3.1 Liver Considerations

Because of poor dietary intake high in sugars and damaged fats, people may have impaired liver function. One very common problem is what is commonly called "fatty liver" or hepatic steatosis. Fatty liver may occur in those with excessive alcohol intake, but a more common problem is non-alcoholic fatty liver (NAFLD). This can be either isolated fatty liver, nonalcoholic steatohepatitis (NASH), or

NAFLD, which is more severe and associated with inflammation, obesity, and metabolic syndrome [24]. Patients often have no symptoms but will probably have abdominal obesity. It can be found via imaging (ultrasound, CT or MRI), or if more severe, via elevated liver enzymes. NASH and NAFLD can progress to cirrhosis as scarring accumulates in the liver tissue. The treatment for fatty liver is primarily lifestyle changes, including abstinence from alcohol, weight loss, and controlling blood sugar. High fructose corn syrup is especially detrimental to the liver and should be eliminated from the diet [25]. Coffee appears to reduce the build-up of scarring in NASH, so it is beneficial [26]. The first-line treatment for non-diabetic NASH is Vitamin E [27]. Other things that may be beneficial include omega-3 fatty acids, N-acetylcysteine (NAC), glycyrrhizin (from licorice root) and whey protein [28–33]. Both NAC and whey protein have high levels of cysteine which can increase glutathione, an antioxidant that is liver-protective. Whey protein may also aid in weight loss.

Other liver diseases include viral hepatitis, chemical hepatitis (such as results from acetaminophen overdose), cirrhosis, and cancer. The presence of any of these can affect the liver's ability to break down toxins by deficiencies in Phase I and Phase II nutrients and by generally overwhelming the detoxification pathways [2].

14.3.2 Kidney Considerations

Chronic kidney impairment can result from diabetes and/or hypertension [34]. The kidneys may also be damaged by direct injury, such as a severe blow or something that decreases blood flow such as an acute hemorrhagic injury that results in significant blood loss. A backup of urine may also damage the kidneys, such as with prostate enlargement, with certain medications or with kidney stones that block the urine outflow. Infections may start in the bladder and ascend into the kidneys which, if not treated promptly, can result in problems such as scarring. Infections from hepatitis, HIV, and strep also may affect the kidneys. Autoimmune diseases, like lupus, that attack body tissues can also damage kidneys. Long-term use of NSAIDS and lead poisoning are other risks.

Kidney impairment can be diagnosed by increased microalbumin in the urine and elevated creatinine in the blood [35]. The estimated glomerular filtration rate (eGFR) is calculated from the creatinine level and considers age, gender, and race. These should be monitored regularly in patients with diabetes and/or hypertension and other chronic medical conditions; keeping blood pressure and blood glucose under good control is paramount. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are commonly used to control blood pressure and reduce proteinuria and are often prescribed for normotensive diabetics for their kidney protective effects.

14.4 Tertiary Approach – Detoxification Support

14.4.1 Start with Food

After protecting the organs of detoxification, the next step is aiding in support of the body's inherent detoxification pathways [36–38]. The baseline issues for patients to enhance detoxification are a clean, good diet and adequate hydration, with clean water providing the best source for fluid intake [36, 37]. Liquids containing caffeine with a diuretic action, such as coffee, soda and, to a lesser extent, tea, result in the body losing more water than is ingested. Caffeinated drinks should not be the primary source of dietary liquid intake. Alcohol also has a diuretic function and inhibits organs of detoxification. Fruit juices are generally high in sugars and not likely healthy choices for detoxification purposes. If patients prefer juice and do not want to eat adequate amounts of vegetables and whole fruit, a blender can be used to make a smoothie with predominantly vegetables and minimal fruit. A juicer that extracts the juice and leaves the fiber behind is not recommended. Fiber is a very important part of the diet in maintaining gastrointestinal health and slowing the absorption of sugars. Vegetables and fruit provide antioxidants and phytonutrients essential for good health [39, 40]. Vegetables should be the mainstay of the diet, especially colorful vegetables such as dark leafy greens, dark yellow, orange, and purple varieties. Fruit also provides important nutrients and fiber, but if used predominantly may provide too much sugar.

Sugar has an inflammatory effect and should be avoided as much as possible [41]. Artificial sweeteners, such as aspartame, have controversial yet concerning effects on human health and should be avoided during detoxification [42]. If added sugar is used, it should be organic cane sugar. Concerns are also raised regarding genetically modified foods (GMO), although this area also remains controversial [43, 44]. We just don't know enough about the safety of GMO foods, but there is emerging research to show there are differences that may be detrimental to health [44]. Sugar beets are a common GMO crop and most of the commercially available sugar uses GMO sugar beets. Corn sweeteners, such as high-fructose corn syrup, are also produced using GMO corn. Because many healthcare practitioners now advise against high-fructose corn syrup and many patients seek to avoid it, manufacturers may refer to it by a different name on food labels [45].

Stevia and monk fruit are safe sweeteners derived from plants [29]. Stevia comes in liquid and powder forms and is a safe sweetener but may have an aftertaste if too much is used. Other sweeteners considered low-glycemic are the GMO or Non-GMO birch or corn derived polyols (examples are xylitol, erythritol, malitol). They contain about 40% fewer calories than sugar and do not cause a rapid increase of blood sugar. They are partially absorbed in the gastrointestinal tract which can produce a laxative or loosening of the stool for some people.

In the 1950s, the role of sugar as an etiology of heart disease began to come to light. However, in 1965, the Sugar Research Foundation paid scientists to do a literature review that downplayed the role of sugar and laid the blame on fat and cholesterol [41]. This led to decades of poor nutritional advice and patients still follow low-fat, low-cholesterol diets to this day. Recommendations to follow a low-fat diet resulted in higher carbohydrate consumption, obesity, metabolic dysfunction, and NAFLD [24]. Rather than low-fat diets, food sources should be rich in beneficial fats. Healthy fats are an important part of the diet (See ▶ Chaps. 10 and 11). Healthy fat ratios should be higher in omega-3 fatty acids rather than omega-6 fatty acids and other fats, like medium-chain fats and omega-9 fats, are to be recommended. Unfortunately, healthy omega-6 fats are not consumed as often as the highly processed damaged vegetable oils which are high in inflammatory omega-6 fatty acids. Processed foods tend to contain fats that are the damaged omega-6 fatty acids and may even contain trans-fats and should be avoided, especially during detoxification. It is important to strike a balance between omega-3 fatty acids and unprocessed omega-6 fatty acids obtained from natural sources. We also now know that saturated fat and cholesterol are not the demons they have been made out to be, but have roles in healthy diets and normal metabolism. Recommended dietary sources of fats include, but are not limited to, coconut oil, olive oil, avocados, grass-fed butter, and fatty fish (wild-caught).

Wheat and gluten have been a subject of much interest in recent years with books like *Wheat Belly* and *Grain Brain* becoming best sellers [46, 47]. Gluten-free products are now found ubiquitously because of the popularity of gluten-free diets. Certainly, the wheat we are using today has been bred to contain more gluten, which is advantageous for bakers wanting to create light, fluffy bakery products. Unfortunately, the gluten, gliadin, and agglutinin found in wheat, especially the modern hybrids, are irritating to the digestive tract and can lead to intestinal permeability, AKA "leaky gut" [46]. The use of glyphosate as a desiccating agent prior to harvest has also been implicated in the rise of gluten intolerance [13, 14]. Intestinal permeability associated with gluten intolerance has been linked to the rise in autoimmune conditions, obesity, and other chronic health problems. Therefore, many detoxification programs recommend eliminating the use of grains, especially wheat.

While some people find that they must completely eliminate grains from their diet, others can tolerate limited amounts without any problems. One of the best ways to determine sensitivity is to try an elimination diet for a period of several weeks. When wheat or gluten is added back to the diet as a challenge, the subsequent reaction – or lack of one – can be evaluated and assessed (See ▶ Chap. 24 for guide to elimination diet). This author has found that, in many patients, eliminating sugars and grains result in a remission of some symptoms, such as gastrointestinal problems, allergic symptoms, and a reduction in chronic pain.

A recent study on long-term gluten-free diets and heart disease indicated that a gluten-free diet increases the risk of coronary heart disease [48]. They concluded that gluten-free diets should not be recommended for people without celiac disease. The answer to this dilemma may reside in the types of food used in substitution of wheat/gluten. Many gluten-free products available to consumers are processed and high in carbohydrates and simple sugars, but not high in fiber and nutrients. This dietary substitution is not particularly conducive to good health. The fiber content of whole grain is a big reason why it is routinely recommended, but it is possible to get high-quality fiber by eating plenty of high-fiber vegetables and fruit. Otherwise, the addition of such high-fiber substances as psyllium husk is an alternative dietary fiber source.

Dairy consumption is another concern during detoxification. In the case of lactose intolerance, dairy sensitivity may be easy to recognize. Casein, the protein in dairy, may also cause intolerance but is more difficult to assess. Regardless, most detoxification programs recommend eliminating dairy. Again, an elimination diet with subsequent challenge is a good way for the patient to see if dairy is contributing to their health problems. If dairy is used, it should be organic.

The diet should contain adequate protein with sources from meat, poultry, fish, eggs, dairy, nuts and seeds, and legumes [49]. The recommended daily allowance (RDA) for protein is 0.80 g/kg per day. This is a minimum amount and a higher intake of protein may be indicated in active individuals to maintain and promote muscle growth. However, most Americans eating a standard diet are easily exceeding the RDA for their protein requirement. Most can obtain adequate good quality protein while reducing the quantity of meat by choosing a predominantly plant-based diet [49]. Protein is essential to support enzymatic detoxification processes because of the amino acids supplied. Patients who might be at risk for not getting enough good quality protein include vegans or those who are severely restricting calories.

14.4.2 Supplementation Use

It is imperative that nutritional counseling be sought to ensure those preparing for detoxification are getting all the necessary nutrients in their diets to support the detoxification process. Because our food may not provide an optimal level of nutrients, a good multivitamin/mineral supplement provides a back-up for what is not received in the diet. Of importance for detoxification are the B vitamins, which are co-factors in many enzymatic reactions. One concern for restricted diets is vitamin B12. Since Vitamin B12 is only found in animal products, those who do not eat animal products will need to use a supplement. As people age, their absorption of Vitamin B12 is lower so older people may also need to take this as a supplement. Magnesium, selenium and zinc are minerals that are frequently deficient and critical for enzymatic conversion of endogenous and exogenous toxins.

Other critical yet deficient nutrients include vitamins D and C. Since a multivitamin/mineral supplement may not provide enough of these critical nutrients, additional supplementation may be needed and can be guided by diet history assessment and laboratory testing.

There are many supplements that are often recommended for detoxification. One common medicinal plant recommended is milk thistle, *Silybum marianum* [29, 50]. This herb has been used for detoxification because of its hepatoprotective properties. It acts as an antioxidant and inhibits the binding of toxins to the hepatic cell membranes and reduces fibrosis. It has been used to treat viral hepatitis as well as to reduce the injury caused by acetaminophen, alcohol, iron overload, and carbon tetrachloride [50].

Another popular medicinal plant, dandelion extract, has also been used for many years for its antioxidant properties and its usefulness in treating liver disorders. Research in rats has confirmed its ability to prevent fibrosis from chemical damage and to promote regeneration [51, 52]. This, in part, is related to its effects on Phase I detoxification pathways, particularly cytochrome P450 2E1. Ginger (*Zingiber officinale*) is another substance that is helpful to prevent fibrosis through its antioxidant capabilities [53–55].

Garlic and vitamin C are useful for many detoxification purposes, but also for reducing lead levels [56–61]. This is especially important for children whose neurodevelopment is damaged by lead toxicity [59]. Garlic has been found to be more effective than d-penicillamine in treating lead poisoning [60].

Glutathione (glutathione S-transferase or GSH) functions as an antioxidant and chelator of metals, including aluminum and mercury, so substances that increase glutathione help with detoxification [62–65]. Spices such as black pepper, curcumin or turmeric, rosemary, and ginger have many beneficial effects, including the potential to increase glutathione levels. Other natural products that may increase glutathione include alpha lipoic acid, chlorella, dark roast coffee, methylsulfonylmethane (MSM), N-acetyl cysteine (NAC), phosphotidylcholine and phosphotidylethanolamine, probiotics with soluble fiber, selenium, sulforaphane (found in cruciferous vegetables), whey protein, and zinc [66–77].

In summary, the approach to detoxification involves three steps: the primary approach – avoidance; the secondary approach – caring for organs of detoxification; and the tertiary approach – detoxification or metabolic biotransformation support. All of these steps promote the health of the detoxification organs and encourage the breakdown and excretion of toxins that will do much to transform the health of your patients and prevent chronic disease.

Prescription and non-prescription drugs have improved the health and well-being of humans. Yet, the potential for alterations in drug performance and/or changes in nutritional status exist. A drug interaction is a situation in which a substance affects the kinetics of a drug or produces a new side effect. Bioactive components in some food have the potential to interact with drugs and either reduce or enhance pharmaceutical effects. Dietary supplements, herbals, and botanicals may contribute additional interactions with drugs. Typically, drug–nutrient interactions are considered adverse side effects [1–4].

> The International Dietetics & Nutrition Terminology Reference Manual [5] defines a food-medication interaction as an 'undesirable or harmful interaction(s) between food and over-the-counter medications, prescribed medications, herbals, botanicals and/or dietary supplements that diminishes, enhances, or alters the effect of nutrients and/or medications.'

Identification of potential risk for drug–nutrient interactions is an essential component of the comprehensive nutrition assessment performed during the nutrition care process. The likelihood of interactions may be increased when the patient is malnourished, has an underlying illness, takes botanical and herbal supplements, consumes alcohol daily, has food allergies or food intolerances, follows a restrictive therapeutic diet, has health beliefs that limit food choices, takes more than two medications, does not follow medication instructions, and/or is a growing child or older adult. Individuals with acute and chronic inflammatory conditions are at risk for sub-optimal serum albumin levels. Albumin is the most important drug-binding protein in the body. Hypoalbuminemia diminishes the number of drug-binding receptor sites and may result in reduced drug bioavailability [3].

It is in the patient's best interest to minimize drug–nutrient interactions. Patients who avoid these interactions are more likely to experience the drug's intended effect and less prone to discontinue taking the drug earlier than recommended. Avoiding drug-induced nutrient deficiencies helps to maintain nutritional status, avoid falls, and injuries that may be caused in part by nutrient imbalances [6, 7].

Not all patients have optimal nutritional status when a new drug is recommended. The undernourished individual may have nutrient insufficiencies that evolve into frank deficiencies due to a drug-induced adverse effect. Malnutrition with loss of lean muscle mass is of concern because of alterations in protein-binding, drug distribution and drug elimination. Drug distribution is the movement of an active drug from the bloodstream to the site of effect. It is affected by a number of factors, including lipophilicity and plasma protein binding. Drug elimination includes metabolism and excretion of the drug.

Malnourished individuals experience loss of fat mass, skeletal muscle mass and visceral muscle mass. The altered body composition has the potential to reduce transport proteins and regulatory hormones involved in drug distribution. The loss of visceral muscle mass contributes to the changes in cardiac output, reduced blood flow to the liver and reduced glomerular filtration rate that may alter drug elimination [8–10].

Individuals taking drugs for a long duration who experience insidious weight loss may be taking drug dosages based on a higher body weight. These individuals are at higher risk for drug–nutrient interactions. In obese patients, there is a risk for accumulation of fat-soluble drugs or a prolonged clearance of drugs resulting in increased risk for drug toxicity.

15.1 Effect of Food and Nutrients on Drug Kinetics and Efficacy

Food and dietary supplements may alter drug kinetics and bioavailability. The bioavailability of a drug is the amount of the drug that reaches systemic circulation. Drugs taken orally have a lower bioavailability than drugs administered intravenously.

The presence of food and nutrients in the stomach and small intestine may increase, decrease or have no effect on the bioavailability of the drug. For example, immediate-release bisphosphonates, such as alendronate sodium, taken with food, significantly reduce drug absorption [11]. However, delayed-release bisphosphonates, such as risedronate delayed-release, may be taken before or after a meal without significantly reducing drug absorption [12].

Furanocoumarins found in grapefruit segments, grapefruit juice, Seville oranges, tangelos, minneolas, and other exotic oranges inhibit the actions of cytochrome P450 enzymes required for oxidative metabolism of numerous drugs. This interaction is of greatest concern for oral drugs with low bioavailability. Moreover, the effects of grapefruit segments and grapefruit juice on the actions of cytochrome P450 enzymes can last up to 72 hours [3, 4].

The presence of food and nutrients in the gut may enhance the drug bioavailability. For example, the absorption of cefuroxime axetil (antibiotic) is increased when taken with a meal versus a fasting state [13]. The bioavailability of iron sulfate supplements is enhanced if taken with food or with ascorbic acid. However, certain food components and nutrients may inhibit iron absorption, including high phytate foods, bran, fiber supplements, coffee, tea, dairy products, and calcium supplements [14, 15].

Drug bioavailability may be altered when achlorhydria or hypochlorhydria persists either due to the action of another drug or because of a medical condition. Drugs used to treat chronic acid suppression raise the pH of the stomach. The higher pH prevents drugs such as ketoconazole (antifungal) from reaching its optimal effect [3, 4]. Table 15.1 summarizes common effects of food and nutrients on drug kinetics.

Table 15.1 Common effect of food and nutrients on drug kinetics

Drug	Food, macronutrient or micronutrient	Potential food–drug interaction
Antibiotics	Milk	Calcium and magnesium in milk may complex with drug and reduce bioavailability [16–18]
Anticonvulsants	Grapefruit juice, grapefruit segments, Seville oranges, tangelos, minneolas, and other exotic oranges	Reduce bioavailability by inhibiting the actions of the cytochrome P450 3A enzymes [19]
Antihypertensives	Licorice	Licorice may cause hypermineralocorticoidism with sodium retention, increased potassium loss, edema, increased blood pressure and depression of the renin-angiotensin-aldosterone system [20]
Calcium channel drugs with Calcium Channe l drugs HMG-CoA Reductase Inhibitors	Grapefruit juice, grapefruit segments, Seville oranges, tangelos, minneolas, and other exotic oranges	Reduce bioavailability by inhibiting the actions of the cytochrome P450 3A enzymes required for oxidative metabolism of numerous drugs [3, 4, 19]
Celiprolol (beta-blocker)	Orange juice	Hesperidin, present in orange juice, is responsible for the decreased absorption [21]
Monoamine oxidase inhibitors	Tyramine-containing foods	Consuming foods containing tyramine with MAOI may trigger a hypertensive crisis [22]
Psychotropics	Grapefruit juice	Components in grapefruit juice interfere with the intestinal efflux transporter P-glycoprotein (P-gp) [23, 24]
Warfarin	Foods rich in vitamin K	Inconsistent intakes of vitamin K rich foods may alter the effectiveness and safety of warfarin [25, 26]
	Cranberry juice	Consumption of cranberry juice is reported to alter the effectiveness and safety of warfarin in some individuals [27, 28]

15.2 Effect of Drugs on Food and Nutrient Kinetics and Nutrition Status

Drugs have the potential to alter food and nutrient intake and kinetics. Nutrients are essential for metabolic processes, and micronutrients reserves, or pools, are quickly depleted when the metabolic rate is increased, absorption and utilization of key nutrients are reduced, or excretion of nutrients is increased.

Drugs have the potential to impact nutrition status in many ways. Many prescription and non-prescription drugs reduce appetite, which reduces total nutrient intake. Other drugs increase the appetite for all food or specific categories of foods, e.g., refined carbohydrates, resulting in excessive energy and refined sugar intake. Moreover, drugs can reduce the absorption of key nutrients in the gastrointestinal tract in a variety of ways, including altering the stomach pH, binding the nutrient into an unusable form, and damaging the absorptive surfaces.

Drugs may increase the metabolism of nutrients, thereby increasing requirements and depleting nutrient reserves. Moreover, drugs may block the conversion of a pre-vitamin to its active form. Key nutrients may be lost in urine and feces. Drugs may increase or decrease urinary excretion. An increase in urinary excretion is typically due to a reduction in reabsorption of the nutrient. Drugs that decrease normal nutrient excretion of sodium may result in water retention.

Drugs that cause damage to the absorptive surfaces have the greatest potential to affect nutrient absorption. Common offenders include chemotherapeutic agents, nonsteroidal anti-inflammatory drugs, and prolonged antibiotic therapy. Table 15.2 summarizes potential drug-induced nutrient deficiencies.

15.3 Role of the Nutrition Professional

Malnutrition and nutrient deficiencies are often viewed as problems unique to developing countries and regions of the world affected by environmental disasters, famine, or political unrest. However, malnutrition and nutrient deficiencies are seen globally. Malnutrition diagnoses may be overlooked because the medical team is not mindful of the potential for nutrient losses to occur. It is essential to recognize that some drug-induced nutrient insufficiencies and deficiencies are insidious and others develop quickly. Drug-induced nutrient deficiencies are compounded by malnutrition. The early signs and symptoms of nutrient insufficiencies and deficiencies are often nonspecific and may be overlooked or misdiagnosed. Laboratory assessments used concurrently with

Table 15.2 Common effects of drugs on food and nutrient kinetics

Drug category	Macronutrient or micronutrient loss	Potential consequences of food–drug interaction
Antacids, magnesium and aluminum, calcium carbonate, proton pump inhibitors (PPI)	Calcium, magnesium, phosphorus, folic acid, copper, iron, vitamin B12	Increased stomach pH and reduced absorption of key nutrients that are best absorbed in the duodenum with a low pH including folic acid [29], calcium, phosphorus, copper, and iron [30, 31]
		It is unclear how PPI's promote hypomagnesemia [30–32]
		Aluminum can bind the phosphate in small intestine, thus lowering serum levels. The body responds by releasing calcium and phosphorus stores from the bones. Calcium levels are tightly controlled in the blood. Excess calcium is excreted in the urine [30]
		Increased pH impairs the body's ability to cleave vitamin B12 from its protein carrier in order to be transported via intrinsic factor (IF). IF is synthesized by the parietal cells in the stomach in the presence of a low pH. An increased pH reduces the synthesis of IF, which will result in reduced absorption of vitamin B12 [33]
Antiarrhythmic: digoxin	Magnesium	Digoxin promotes increased renal excretion of magnesium [34]
Antibiotics, sulfonamide combination drugs	Folic acid	May interfere with folic acid metabolism if taken for a prolonged period of time [35]
Antibiotics, fluoroquinolones	Magnesium, iron, zinc, calcium	Drug binds to iron, magnesium, zinc, and calcium creating insoluble complexes [36, 37]
Antibiotics, tetracyclines	Magnesium, iron, zinc, calcium, vitamin K, B complex vitamins	Drugs binds to iron, magnesium, zinc, and calcium creating insoluble complexes. May reduce bacterial synthesis of vitamin K2, menaquinone, in the colon. Long-term use may result in depletion of B vitamin stores [38]
Anticonvulsants	Vitamin B6, vitamin B12, folate	May interfere with vitamin B6, vitamin B12, and folate absorption, resulting in lower serum levels [39, 40]
Anticonvulsants	Biotin	May accelerate catabolism of biotin resulting in lower serum levels [41]
Anticonvulsants	Vitamin D	Lower serum levels reported possibly related to low bone density and osteomalacia [42]
Anticonvulsants	Calcium	Reduced absorption possibly related to vitamin D deficiency [43]
Anticonvulsants	Vitamin K	Drugs may decrease half- life of vitamin K and impair its key functions [44, 45].
Antihyperglycemic metformin	Vitamin B12	Metformin appears to inhibit the absorption of vitamin B12 [46]
Antihypertensive: ACEI angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker	Zinc	ACEI and ARB therapy has been shown to increase urinary excretion of zinc [47]
Antihypertensive: ACEI angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker	Potassium	ACEI and ARBs are associated with increased serum potassium, which may or may not be offset by the reduction of potassium due to loop diuretics [48, 49]
Antihypertensive: hydralazine	Vitamin B6, copper	Hydralazine may interfere with vitamin B6 metabolism. It may promote increased excretion of copper [50, 51]
Antihypertensive: RAAS renin-angiotensin-aldosterone system	Potassium	RAAS have the potential to cause hyperkalemia by interfering with the production and secretion of aldosterone [52–56]
Antimanic: lithium	Sodium	Lithium may increase sodium excretion [57]

Table 15.2 (continued)

Drug category	Macronutrient or micronutrient loss	Potential consequences of food–drug interaction
Antineoplastic: methotrexate	Folic acid	Methotrexate is a folic acid antagonist that interferes with nutrient utilization [58, 59]
Antiplatelet agents	Iron, folic acid, sodium, potassium, vitamin B12	Long-term use associated with reduced levels of iron, folic acid, sodium, potassium, vitamin B12 [60, 61]
Antipsychotics, phenothiazine class, tricyclic antidepressants	Riboflavin	Drug increases the excretion of riboflavin that may lead to deficiency in individuals with insufficient riboflavin intakes [62]
Antitubular: isoniazid	Vitamin B6, niacin (B3), vitamin D, calcium, phosphate	Drug may deplete vitamin B6 and niacin stores resulting in peripheral neuropathy and pellagra [63, 64]
		May impair vitamin D metabolism and consequently reducing calcium and phosphate absorption [65]
Beta-adrenergic blockers (beta-blockers)	Potassium	Beta-blockers have the potential to cause hyperkalemia by causing redistribution of potassium from the intracellular space into the serum [66, 67]
Beta-2 agonists	Magnesium, potassium	Reduced serum levels of magnesium and potassium reported. The degree of deficiency is exacerbated when beta-2 agonist is taken with theophylline [68, 69]
Bile acid sequestrants	Vitamins A, D, E, K, beta-carotene, iron	Bile acid sequestrants bind fat soluble vitamins, beta-carotene, and iron [70]
Bile acid sequestrants	Magnesium, iron, calcium, zinc and folic acid	Alterations in calcium, magnesium, and zinc metabolism may be explained by inadequate vitamin D absorption in the duodenum followed by an increased secretion of parathyroid hormone [71]
Bronchodilator: theophylline	Vitamin B6, potassium, magnesium	Reduced levels of pyridoxal phosphate may be related to altered tryptophan metabolism or impaired vitamin B6 utilization. Reduced levels of potassium and magnesium have been reported, possibly related to increase urinary excretion [72–75]
Colchicine (antigout)	Vitamin B12	In animals, colchicine may reduce vitamin B12 absorption and efficiency of ileal receptor sites leading to a vitamin B12 insufficiency or deficiency [76, 77]
Diuretics: loop	Sodium	Loop diuretics reduce sodium reabsorption in the proximal tubule. Patients who are prescribed a sodium-restricted diet as part of medical management of hypertension are at greater risk of hyponatremia [57]
Diuretics: loop	Potassium	Loop diuretics reduce potassium reabsorption at the site of action and enhance potassium secretion in the distal tubules of the nephron. In addition, aldosterone can also contribute to hypokalemia after administration of loop diuretics [78]
Diuretics: loop	Magnesium	Loop diuretics reduce magnesium reabsorption in the loop of Henle and proximal tubule. It is also dependent on sodium and chloride concentrations. Magnesium depletion promotes the efflux of potassium from cells and subsequent urinary excretion [79–81]
Diuretics: loop	Thiamine	Long-term use is associated with reduced levels of thiamine. Loop diuretics promote thiamine losses up to twice baseline loss. Increased loss is associated with an increase in urine flow rate, but it is not related to sodium excretion. Up to 1/3 of CHF patients were found to be thiamine deficient [82–88]
Diuretics: loop	Zinc	Long-term use of loop diuretics reduce zinc reabsorption in the proximal tubule [89]
Diuretics: loop	Calcium	Loop diuretics reduce calcium reabsorption in the proximal tubule. It is also dependent on sodium and chloride concentrations [90]
Diuretics: thiazide	Calcium	Thiazide diuretics reduce calcium reabsorption in the proximal tubule. It is also dependent on sodium and chloride concentrations [90]

(continued)

Table 15.2 (continued)

Drug category	Macronutrient or micronutrient loss	Potential consequences of food–drug interaction
Diuretics: thiazide	Sodium	Thiazide diuretics reduce sodium reabsorption in the proximal tubule. Patients who are prescribed a sodium-restricted diet as part of medical management of hypertension are at greater risk of hyponatremia [57]
Diuretics: thiazide	Potassium	Thiazide diuretics reduce potassium reabsorption at the site of action and enhance potassium secretion in the distal tubules of the nephron. In addition, aldosterone can also contribute to hypokalemia after administration of loop diuretics [91]
Diuretics: thiazide	Magnesium	Thiazide diuretics reduce magnesium reabsorption in the loop of Henle and proximal tubule. It is also dependent on sodium and chloride concentrations. Magnesium depletion promotes the efflux of potassium from cells and subsequent urinary excretion [79–81]
Diuretics: thiazide	Zinc	Long-term use of thiazide diuretics reduce zinc reabsorption in the proximal tubule [92]
Glucocorticoids	Zinc	Glucocorticoids may promote development of zinc deficiency in some patients [89, 90]
Glucocorticoids	Calcium, Chromium	Glucocorticoids increase urinary losses of chromium and calcium [93, 94]
Immunosuppressant: cyclosporine	Magnesium	Cyclosporine promotes renal magnesium wasting [95]
Immunosuppressant: Hydroxychloroquine	Vitamin D	Hydroxychloroquine may inhibit the conversion of 25-hydroxyvitamin D to the active form, i.e., 1,25 dihydroxyvitamin D [96]
Laxatives, cathartics	Calcium, potassium	Laxatives reduce transit time in the gut leading to diarrhea and increased fecal loss of calcium and potassium [97]
Mineral oil laxatives	Vitamins A, D, E, K	Mineral oil-based laxatives may reduce the absorption of fat soluble vitamins [98]
Peripheral vasodilator	Vitamin B6	Peripheral vasodilators interfere with vitamin B6 metabolism and may result in lower levels [50, 99]

nutrition-focused physical exams are essential tools to detect drug-induced nutrient insufficiencies and deficiencies.

The nutrition professional's approach to detect drug-induced nutrient insufficiencies and deficiencies is determined by the patient's health history. For example, patients who are starting on a new drug are looked at prospectively. The nutrition professional uses clinical judgment to predict the potential for drug-induced nutrient insufficiencies and deficiencies by identifying specific strategies and interventions to prevent or compensate for nutrient losses. Moreover, foods or food intake patterns associated with reduced drug absorption are identified and discussed as part of patient education. The nutrition professional will monitor the readiness of the patient to incorporate specific strategies and interventions as well as the health outcomes. Adjustments in the interventions are often required.

Patients who have been on specific drugs for an extended period of time are assessed retrospectively. The nutrition professional uses clinical judgment to detect signs and symptoms of drug-induced nutrient insufficiencies and deficiencies using historical data. Trends in laboratory results may indicate suspected nutrient insufficiencies that are confirmed with nutrition-focused physical exam. Specific interventions are recommended by the nutrition professional to compensate for nutrient losses. Monitoring and evaluation of changes in nutrition status are essential to determine the efficacy of interventions.

The nutrition professional does not work in a vacuum. As a member of an integrative healthcare team, the nutrition professional provides valuable insight and findings to improve the health and well-being of patients.

Derivation of the name

Enteron - Intestine (Greek)

Hepar - Liver (Greek)

16.1 Enterohepatic Circulation (EHC) - Definition

The circulation of bile acids, bilirubin, drugs, or other substances from the liver to the bile, followed by entry into the small intestine, absorption by the enterocyte and transport back to the liver. Recycling through liver by excretion in bile, reabsorption from intestines into portal circulation, passage back into liver, and re-excretion in bile [1].

16.2 Introduction

The purpose of this chapter is to provide insight into the functioning of the enterohepatic circulation (EHC) as it relates to the practice of clinical nutrition. The focus will not be on disease management; rather, it will be on ways in which improving the health and function of the tissues and organs of the EHC might be approached.

Health professionals, of any level of training or experience, are the intended audience. To be inclusive, the content may be helpful for those who aspire to become health professionals, those who want to understand human physiology in greater depth and anyone who is interested in learning how to create a better state of health. This chapter should help those with training in conventional Western medicine who employ a "mainstream" approach to healthcare, but who feel that there is more to patient care than they are equipped to deliver. It should help open channels of communication and new thought processes to investigate ways to deliver patient-focused healthcare and guide the practitioner to find a new group of like-minded professionals.

The foundation of what we do is basic science. Yet science is always growing. What we know now about the EHC is vastly different from what was known in 1923, the date of one of the earliest publications on the subject [2]. The role of the EHC in the recirculation and conservation of bile salts is foundational and was known from the beginning. But the awareness that the EHC also handles hormones, drugs, and other substances, both endogenous and exogenous, emerged over the next 40 years [3–8]. In the subsequent 50 years, these topics have been extensively studied and documented. The role of the EHC in the metabolism of xenobiotics (see below) began to emerge later. The first use of the term "xenobiotic" in the Medline database was in 1965 [9].

The term gut "microbiome" first appeared in 2002, and it became clear that colonization with healthy bacteria is critical for the normal structural and functional development, and the optimal function of the mucosal immune system [10]. Other areas of important research include the relationships between the microbiome, the gut-associated lymphoid tissue, the enteric nervous system, and the enteric endocrine cells in regard to their systemic effects [11, 12]. The metabolic effects of bile acids are also garnering increased attention [13, 14]. Thus, understanding of the functions of the EHC has increased dramatically over nearly 100 years, and we can only expect this to continue.

16.3 Overview

To refresh our understanding of the structure of the EHC, the following drawing and comments will provide an overview. The purpose of this section is to provide a basic, common understanding of the EHC as a system (Fig. 16.1).

16.4 Details of Microanatomy, Physiology, and Biochemistry

The following sections will present a much more detailed understanding of some of the individual components of the EHC, how they relate together, and how the EHC interacts with the rest of the body. This will help provide a framework for further study, and to provide a foundation for understanding why nutrition needs to be incorporated into the root of medical education. In one sense, nothing said here is new, but will aid in expanding understanding of nutritional therapies [15].

16.4.1 Portal Vein

The portal vein and its tributaries drain the entire intestinal tract from the gastroesophageal (GE) junction at the top of the stomach, all the way to the anus. This is a distance of 33 feet (11 yards) in the average adult. Through these veins, all the blood flowing from the stomach, small, and large intestines is carried directly to the liver. Veins, in general, carry blood toward the heart. In the case of the portal vein and its tributaries, the blood ultimately reaches the heart, but after being processed in the liver. This portal venous system is separate from and parallel to the systemic veins, which carry blood from all the other organs and tissues in the body directly to the heart.

16.4.2 Portal Tracts

In the liver, the portal vein branches like a large tree. The tiniest branches are called portal venules, which travel through the liver in a network of fibrous channels called portal tracts. In addition to the portal venules, the portal tracts carry tiny arterioles from the hepatic artery, which carry highly oxygenated blood directly from the heart. About 70% of the blood supply to the liver comes from the portal venules and so from the intestines, the remaining 30% from the hepatic arterioles (Fig. 16.2).

Also coursing through the portal tracts are bile ductules, which carry bile out of the liver; lymphatic channels, which

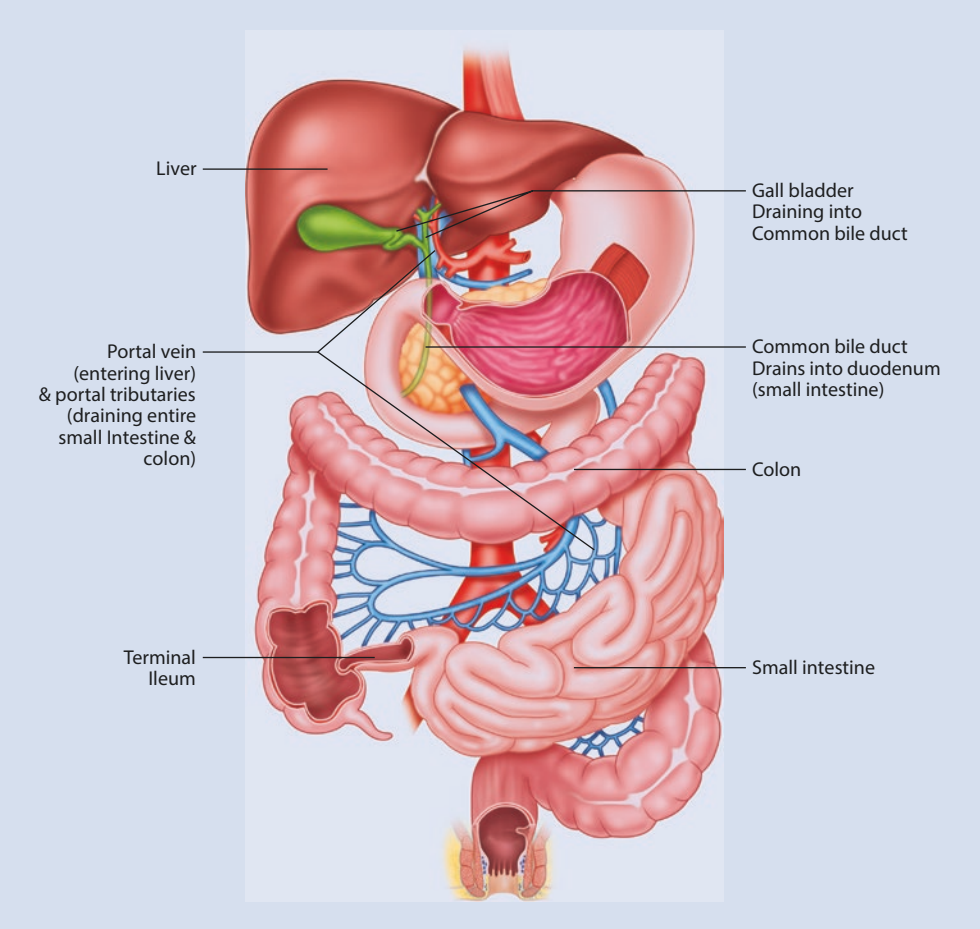

Fig. 16.1 (1) *Portal vein & portal tributaries*. Carries blood from the intestinal tract into liver; (2) *Liver*. Functions: nutrients synthesized into metabolic compounds transported and utilized by organs; detoxification processes; stabilization of blood glucose; synthesization of ATP; bile production; (3) *Bile ducts and gallbladder*. Bile, the main secretory product of the liver, is stored and processed in the gallbladder; (4) *Small intestine*. Duodenum: first part of the small intestine receiving bile and pancreatic enzymes; jejunum and ileum: second and third portions of the small intestine where digestion occurs; (5) *Terminal ileum*. Final 6 inches of the small intestine where 95% of the bile is absorbed and recirculated to the liver, historically the origin of the term enterohepatic circulation; (6) *Large intestine or colon*. The final five feet of the intestine where stool is concentrated, other metabolic processes occur, and the resulting feces are discharged through the anus; further absorption of bile also occurs, entering the portal circulation. (Adapted from [49]. With permission from Wolters Kluwer Health)

carry lymphatic drainage away from the liver; and branches of the autonomic nervous system, evidence of the input of the autonomic nervous system into functioning of the liver on a cellular level.

16.4.3 Liver/Hepatic Lobule

Viewed under light microscopy, the liver parenchyma consists primarily of a single cell type, the hepatocyte or liver cell. Hepatocytes occur in extensive sheets of cells with an essentially uniform appearance, which are interwoven with the hepatic sinusoids. (See section below) The classic unit of hepatocyte organization is called the hepatic lobule. This structure is composed of six portal triads and a central vein, and can be seen under the microscope. However, because the lobule is a three dimensional structure in vivo , the classic hexagonal lobular structure is seldom seen in photomicrographs of a 2-dimensional cut section.

Each lobule consists of an average of six portal tracts forming the corners of a hexagon made up of hepatocytes, with a central hepatic venule (CV) or terminal hepatic venule (THV) located approximately in the center. Blood enters through the portal tracts at the periphery of the lobule, flows into the sinusoids adjacent to the hepatocytes, is processed while traversing the sinusoid, and then empties into the central hepatic venule. The central hepatic venule is the smallest branch of the hepatic vein, which carries blood back to the heart.

16.4.4 Hepatic Sinusoids and Hepatocytes

Exiting the portal tracts, blood from the portal venules merges with blood from the hepatic arterioles and flows into a vast vascular web called the hepatic sinusoids, which extend throughout the liver (Fig. 16.3). Blood flow into the sinusoids is regulated by specialized tissues in the portal venules and hepatic arterioles as they emerge from the portal tracts. Hormones, autonomic nervous input, and other factors influence this sinusoidal blood flow. Part of the cell membrane of each hepatocyte (the basolateral membrane) is adjacent to a sinusoid. It is through this basolateral membrane that transport of molecules into the hepatocytes occurs for processing.

16.4.5 Interaction of Sinusoidal Blood with the Hepatocyte Basolateral Cell Membranes

In the sinusoids, the liquid part of the blood, the serum, bathes the basolateral membranes of the hepatocytes. These cell membranes are highly specialized to carry out specific

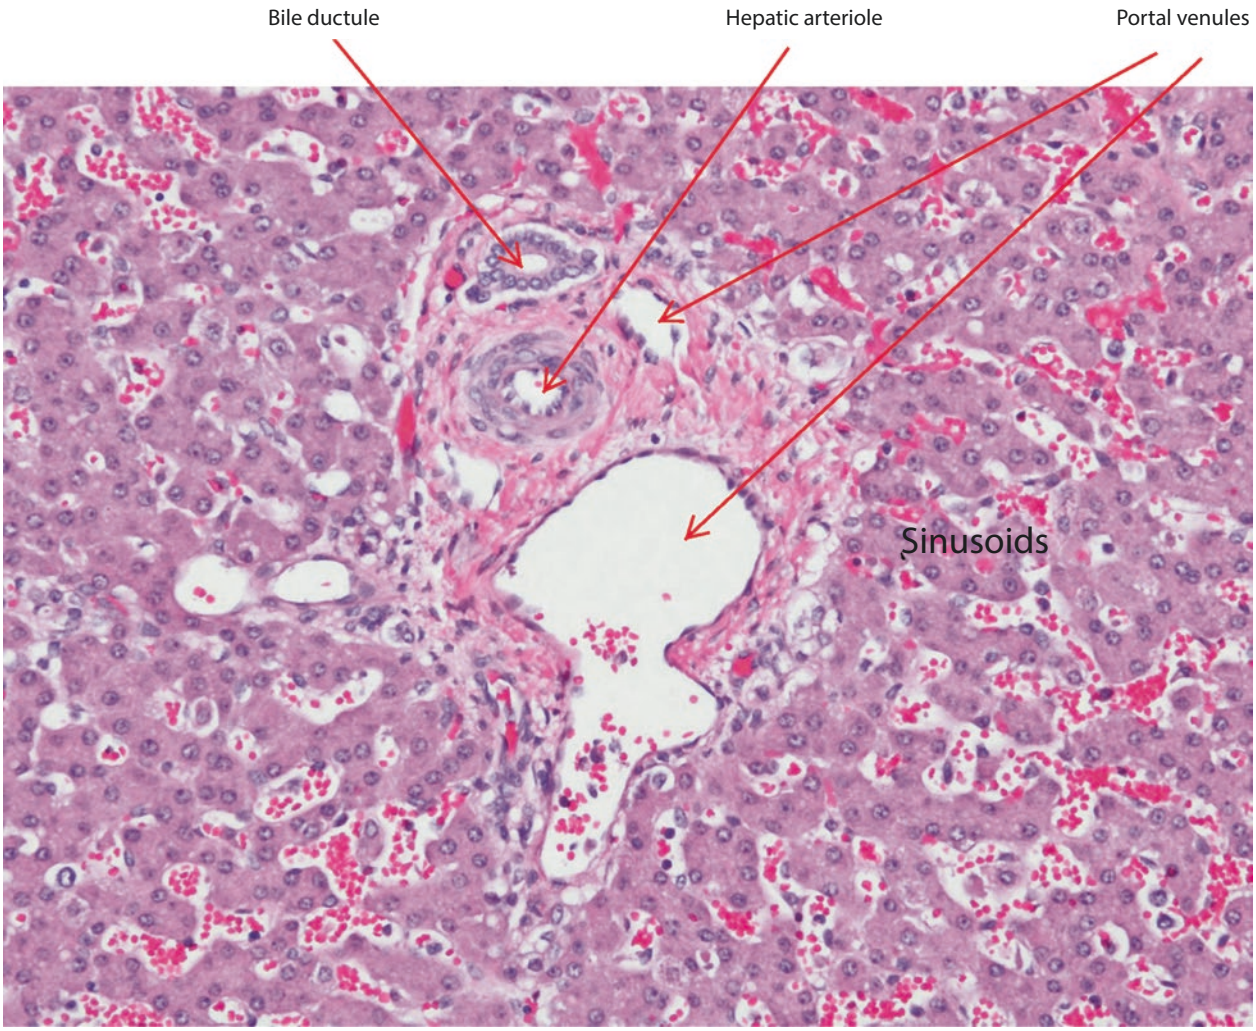

Fig. 16.2 (Portal tract photo) Portal tracts course in a vast network through the liver with the terminal branches of the portal venules carrying blood from the intestinal tract and hepatic arterioles carrying highly oxygenated blood from the heart. Portal blood mixes with hepatic arteriolar blood and flows into the sinusoids. Lymphatic channels and branches of the autonomic nervous system are not visible in this photomicrograph. The cells around the portal tract and adjacent to the sinusoids are periportal hepatocytes in which many synthetic and energy-producing steps occur. (Courtesy of Beverly B. Rogers MD, Emory University School of Medicine)

functions, and these functions vary as the blood flows through the sinusoids. As with cell membranes throughout the body, the basic hepatocyte cell membrane structure consists of molecules called phospholipids. Cholesterol is also a vital membrane component. Membranes are highly structured, yet fluid and flexible. Studding the membranes are hundreds of different types of transport channels, usually constructed from proteins, which allow molecules to move in and out of the hepatocytes in coordinated fashion.

Interactions of serum molecules with the basolateral cell membrane transport channels are not haphazard or random. As with cell membranes anywhere in the body, enzymes which comprise the transport channels seem to have a specific affinity for molecules they transport based on many factors, including pH, electrostatic forces, molecular size and folding (S Finnegan, Research on lactase and carbohydrase enzymes (Lactaid and Beano), Quality Control Director, Body Bio Corporation, personal communication, 2016; R Silva, Emeritus Professor of Chemistry, California State University Northridge, personal communication). In other words, interactions between serum molecules with the basolateral membrane of hepatocytes are not simply random collisions. There are dynamic and specific interactions which direct individual molecules to their corresponding transport channels so the processes of hepatic metabolism can proceed in orderly fashion. Other aspects of the sinusoidal anatomy (fenestrated endothelial cells, space of Disse, Kupffer cells, stellate cells, and others), although fundamental and vital, will not be discussed here, and the reader is referred to texts to expand knowledge.

16.4.6 Metabolic Zonation/Organization of Hepatocytes by their Function

The first article on metabolic zonation was published by Katz and Jungermann in 1976 [16]. Techniques have since been developed whereby the hepatocytes adjacent to the portal tract (periportal hepatocytes) and those adjacent to the cen-

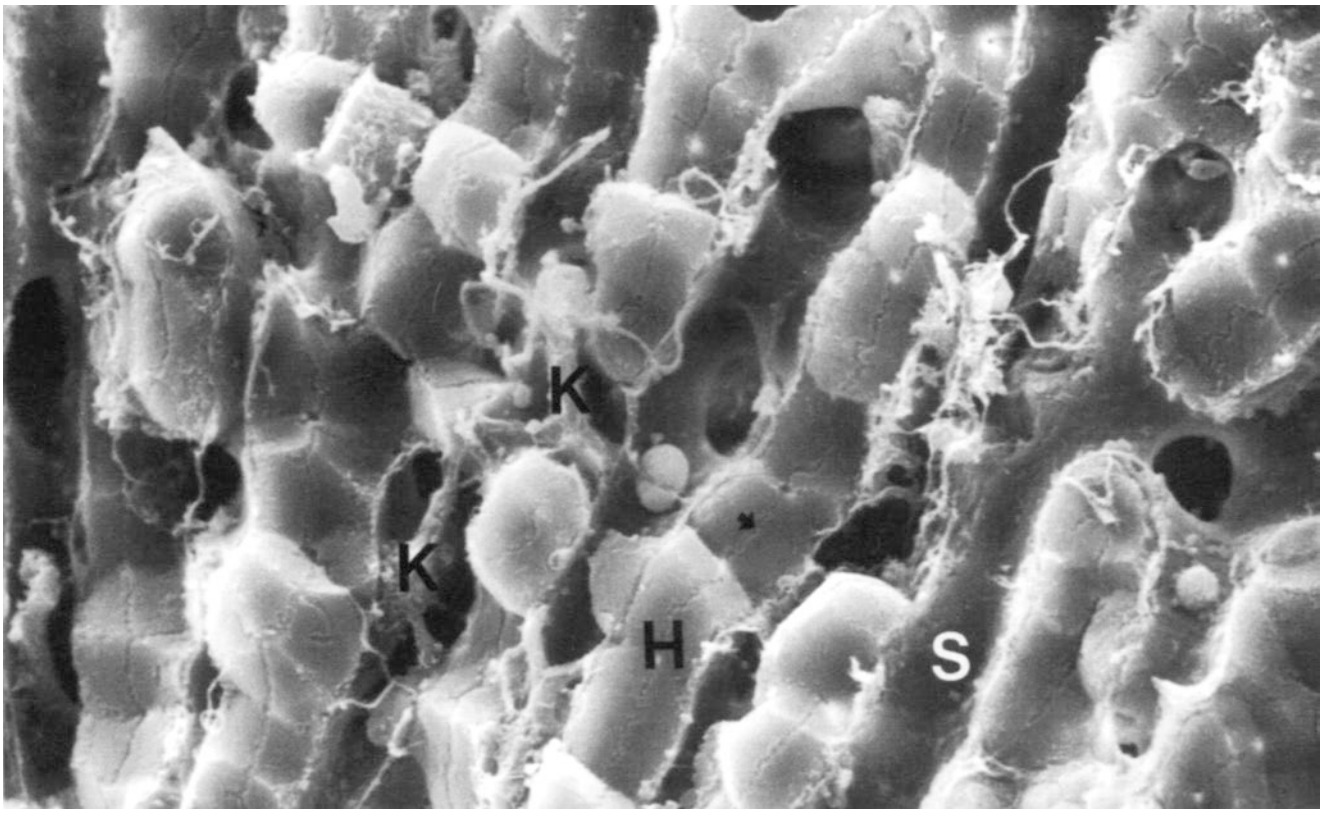

Fig. 16.3 (Sinusoid photo) Scanning electron micrograph showing rows of hepatocytes (H) adjacent to hepatic sinusoids (S) with bile canaliculi visible as small, winding grooves visible on the surface of some of the hepatocytes. (The cells designated K are kupffer cells, and are not discussed here.) (Reprinted from Schiff et al. [50]. With permission from Wiley)

tral vein (perivenular hepatocytes) can be isolated from one another, and their properties studied [17]. The hepatocytes in a liver lobule vary in their function, depending on their position along the path from the portal tract to the central venule. The generally uniform appearance of the liver under light microscopy does not accurately depict the highly specialized and tightly regulated functions of different hepatocyte populations (Fig. 16.4).

While the hepatic lobule describes structure, the concept of the liver acinus, first put forth by Rappaport [18], is related to hepatocyte function. Periportal hepatocytes have a higher oxygen content and perform different metabolic functions compared to perivenular hepatocytes. Rappaport called the periportal area, Zone 1, the perivenular area, Zone 3, with Zone 2 representing the intermediate area between Zones 1 and 3 [17, 18].

In their study on the microvasculature of the liver, Matsumoto and Kawakami found the organization of the vascular flow through the sinusoids is reflected in the precise detail seen on the microscopic level [19]. What might otherwise seem like a random flow of blood from the portal venules and hepatic arterioles into the liver parenchyma via the sinusoids is, in fact, a highly structured hemodynamic process which feeds the blood flow through the sinusoids in an organized fashion, with the resulting effluent flowing into the central hepatic venules [19, 20]. The results of their findings are congruent with the acinus concept, with periportal and perivenular hepatocytes performing different functions.

Zone 1 (Z1) is more highly oxygenated than Zone 3 (Z3) [17]. Many details of metabolism in Z1 and Z3 have been identified (Fig. 16.5), but there is much yet to be discovered. The details of this metabolic zonation can vary from time to time. Some of the driving forces have been identified, including oxygenation, pH, hormones, nutrients, metabolites, cytokines, and molecules called morphogens, the most well-known of which is named Wnt (beta) catenin, [17].

In summary, at the microscopic level of function, the complex processes of hepatic metabolism are proceeding and constantly adjusting to both what is delivered from the portal circulation and to inputs from the rest of the body, including hormonal signals and those from the autonomic nervous system.

16.4.7 Functions of the Liver

The liver is the most potent synthetic factory in the body and a significant organ for waste processing and disposal. See Table 16.1 for a summary of some of the important functions.

16.4.8 Xenobiotics

The term "xenobiotic" is derived from two Greek words, *xenos* meaning foreign or strange, and *bios* meaning life.

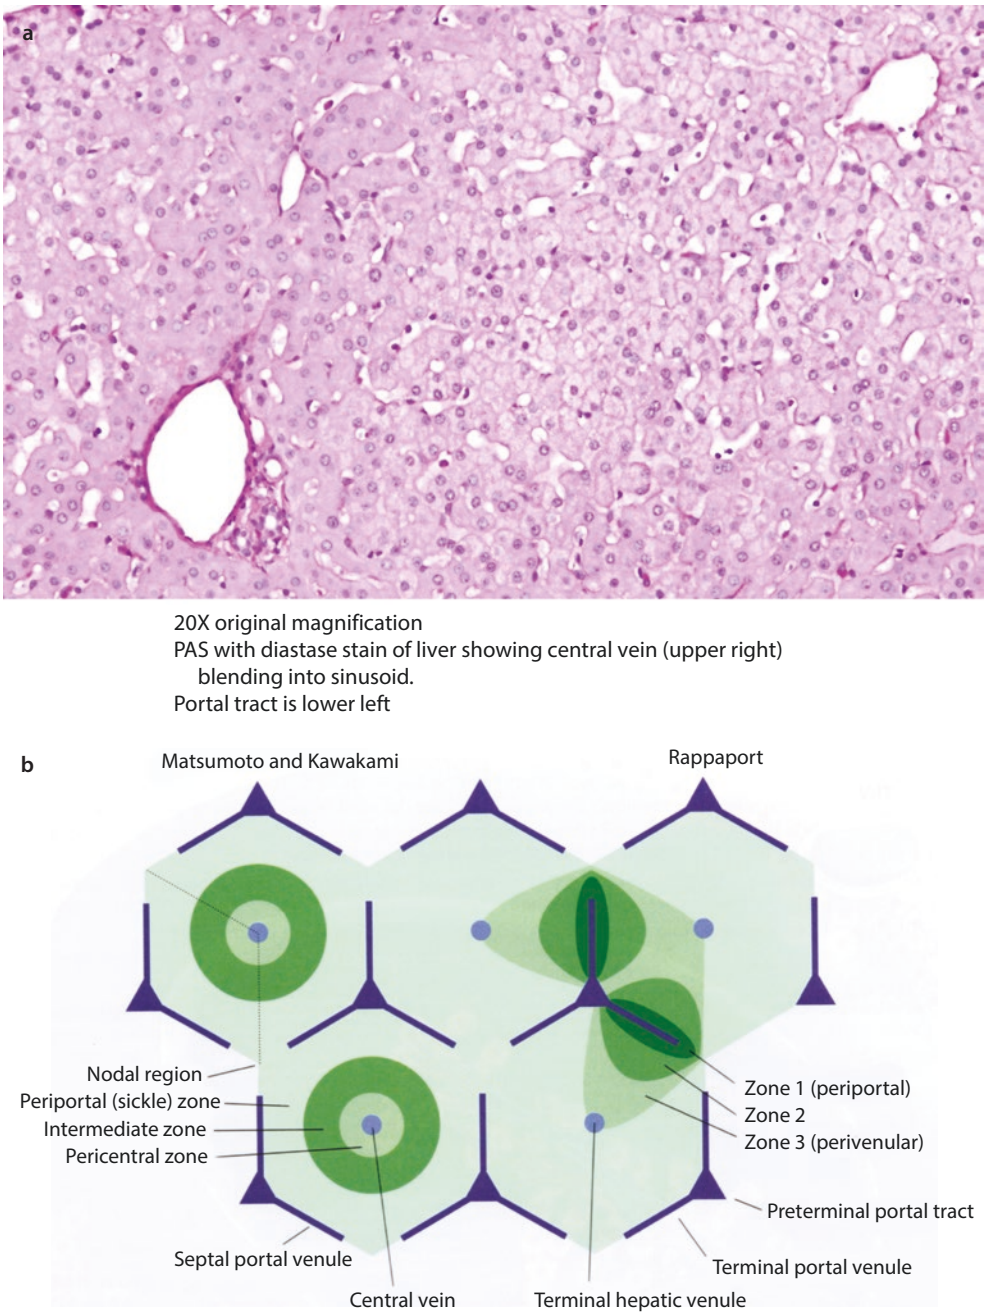

Fig. 16.4 [Hepatic lobule photomicrograph (**a**) and drawing (**b**)]. (**a**) Photomicrograph: Portal tract (lower left) and central venule (upper right) with sheets of hepatocytes interspersed with the intervening vascular sinusoids. Blood entering the liver through the portal tract flows into the sinusoids where it is processed and flows out of the liver through the central venule. Hepatic lobules typically consist of six portal tracts. (**b**) Diagram: Depiction of five classic hepatic lobules. Triangles correspond to portal tracts, from which blood flows to centrally located central venules; detailed microvascular work of Matsumoto and Kawakami contribute to concept of the hepatic acinus proposed by Rappaport; metabolic functions occur in these hepatic lobular structures. (**a**) (Courtesy of Beverly B. Rogers MD, Emory University School of Medicine). (**b**) (Reprinted from Schiff et al. [50]. With permission from Wiley)

Xenobiotic can be defined as a chemical compound foreign to a given biological system. With respect to animals and humans, xenobiotics include drugs, drug metabolites, and environmental compounds such as pollutants that are not produced by the body. In the environment, xenobiotics include synthetic pesticides, herbicides, and industrial pollutants that would not be found in nature [21]. For further information see ▶ Chap. 13.

An important functional distinction is that molecules absorbed from the small intestine and transported to the liver can be viewed as either "nutrients" or "xenotiobitcs". A nutrient molecule, once it reaches the liver, does not require further breakdown or processing to be used metabolically. Examples of nutrients include amino acids from proteins, monosaccharides from complex carbohydrates, and cholesterol. In the hepatocyte, nutrients can be used in synthesis of macromolecules (building blocks for the body), metabolized through the electron transport chain to produce ATP, and for other purposes.

A xenobiotic, on the other hand, must undergo a process called biotransformation. The products of biotransformation are excreted from the liver in the bile, or in a minority of cases, sent into the systemic circulation, where some accumulate in other organs including the brain, liver, lung, fat, kidney, and/or bone (See ◘ Table 16.2).

16.4.9 Where Are Xenobiotics Found?

We are exposed daily to many harmful environmental chemical toxicants. The Centers for Disease Control and Prevention

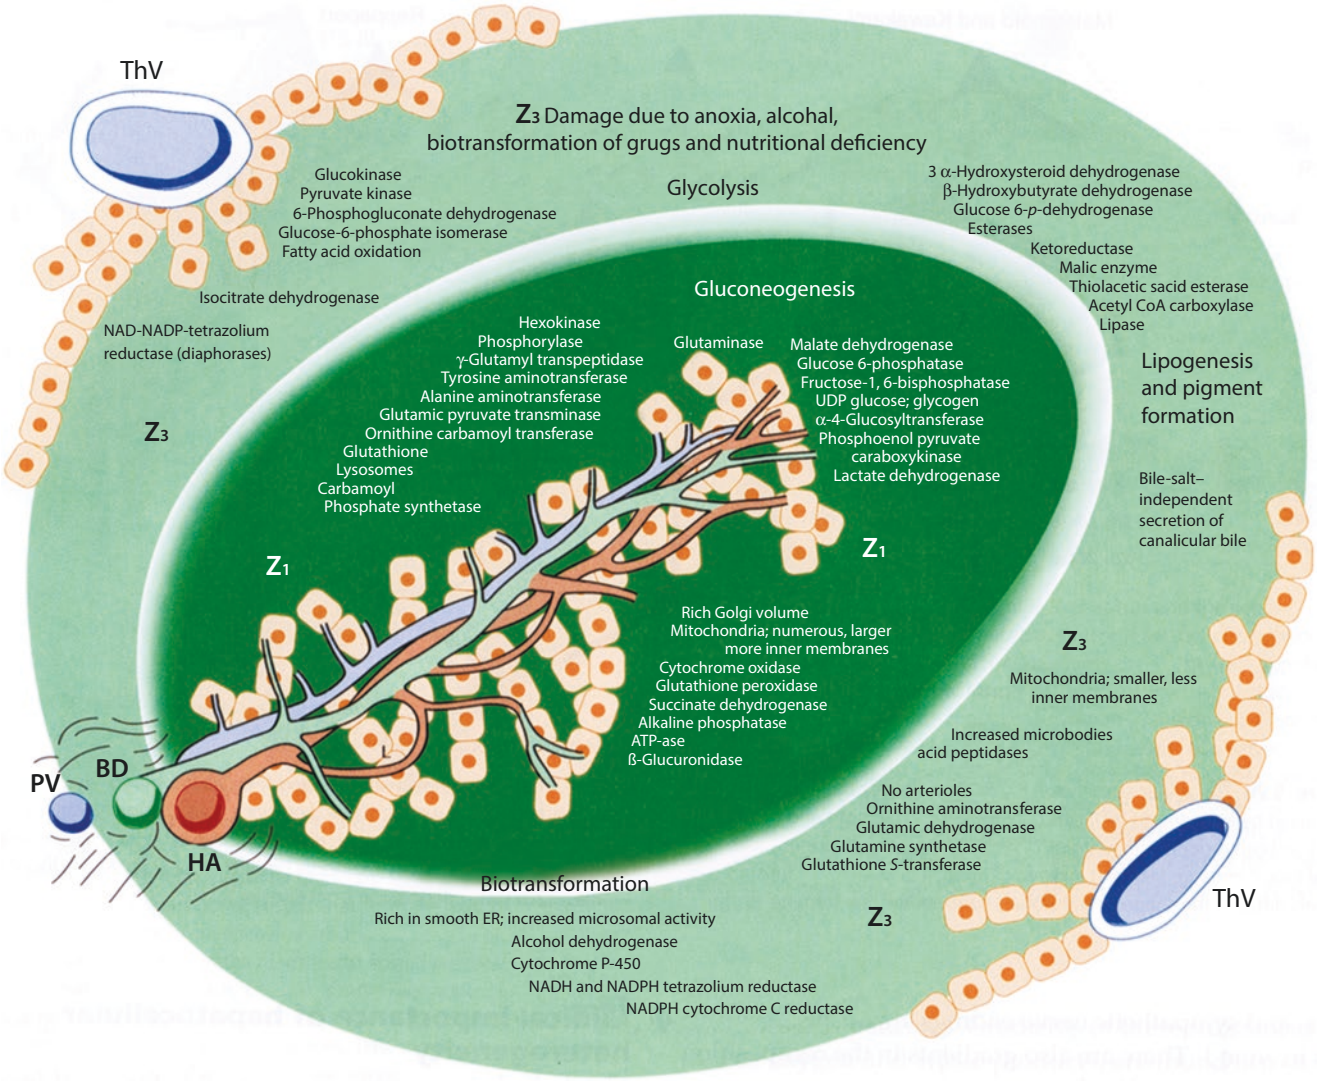

Fig. 16.5 (Schiff Z1 and Z3 characteristics) Diagram depicting some of the known metabolic processes occurring in Zone 1 (periportal) and Zone 3 (perivenular) of hepatic lobules. Zone 1, biosynthetic and energy producing processes; Zone 3, biotransformation enzymes which metabolize xenobiotics. Blood flowing from the portal tracts is first exposed to the hepatocytes in Zone 1, periportal areas, ultimately reaching Zone 3, the perivenular hepatocytes. (Reprinted from Schiff et al. [50]. With permission from Wiley)

(CDC) lists 265 environmental chemicals, many of which were shown to be present not just in the environment, but in the tissues of individuals studied [22]. It would be profitable for the reader to access the CDC report and scan through it to get a sense of the vast number of xenobiotics modern humankind is exposed to and understand this report gives only a partial listing. The report details xenobiotic exposures that may be present from multiple sources, including air, water, food, skincare products, and cleaning chemicals, and from a vast number of industrial sources that find their way into homes and the environment.

16.4.10 A Few Examples of Problems Caused by Xenobiotics

One of the first papers linking the harmful effects of environmental chemical exposures with fetal development was diethylstilbestrol which showed the exposed individual's subsequent risk in the development of vaginal cancer [23]. Subsequently, a consensus statement from the Wingspread Conference in 1991 began with this statement, "We are certain of the following: A large number of manmade chemicals that have been released into the environment, as well as a few natural ones, have the potential to disrupt the endocrine system of animals, including humans" [24]. One important approach to mitigating the problem of harmful xenobiotic exposures is addressing the liver's biotransformation enzyme systems, through which they are processed.

16.4.11 Biotransformation

In the liver, xenobiotics, that is any molecules not treated as a nutrient, are processed through the biotransformation enzymes [25]. These biotransformation enzymes are located

Table 16.1 Important functions of the enterohepatic circulation and the liver

Proteins (including albumin), lipids (fats, including cholesterol) and complex carbohydrates are synthesized and transported out of the liver
Production of ATP, the principle energy storage molecule in the body, via the electron transport chain
Bile acids formed and secreted into the biliary system; also perform metabolic functions within the hepatocytes
Glucose homeostasis occurs in the balance between gluconeogenesis (formation of the storage molecule glycogen) and glycolysis (release of glucose from glycogen)
Foreign substances (xenobiotics) are metabolized, mostly into nontoxic substances, which can be secreted into the bile or sent to long-term storage depots elsewhere in the body
Important communication functions carried out by hormones and the autonomic nervous system

Table 16.2 Classes of xenobiotics

Food additives
Pharmaceuticals
Environmental pollutants, including many categories of synthetic molecules
Heavy metals
Genetically modified foods; unless the GMO modifications produce nutrients, which are native to the human body, these foods fall into the category of xenobiotics

almost exclusively in the perivenular hepatocytes, Z3, in the liver acinus. Most xenobiotics are fat-soluble, serve no useful physiological purpose, and must be eliminated from the body. In most situations, this occurs in a two-step process.

Phase I biotransformation (detoxification) occurs in the smooth endoplasmic reticulum of the perivenular hepatocytes. Most commonly, once a xenobiotic molecule enters the hepatocyte, it encounters the cytochrome P450 enzymes, which convert the molecule into a highly energetic intermediate. These intermediates are then metabolized by Phase II biotransformation enzyme pathways. The names of these pathways are sulfation, glucuronidation, acetylation, methylation, amino acid conjugation, and glutathione conjugation [25].

The majority of the products of Phase II enzymatic reactions are secreted into the bile. A small percentage of the excretory products from the hepatocyte do not go into the bile; they are secreted back through the basolateral membrane into the sinusoid, from which they enter the systemic circulation and are carried to other organs and tissues. This most likely represents the pathway by which heavy metals (lead, mercury, cadmium, etc.) reach and are ultimately stored in other organs, such as the brain, kidney, lung, bone, and the liver itself. Please see ► Chap. 13 for more in-depth discussion.

16.4.12 Cytochrome P450 Genes and Enzymes

The cytochrome P450 enzymes (CYP 450) are numbered to indicate a specific group within the gene family, a letter indicating the gene's subfamily, and a number assigned to the specific gene within the subfamily. A specific CYP gene codes for the corresponding CYP enzyme. As of 2012, there were 57 human CYP enzymes, each with its specific propensity to metabolize certain categories of xenobiotics [25–27]. One example would be CYP 450 2D6, which is one of the cytochromes responsible for metabolizing hypertensive drugs. Another is CYP 450 2E1, which plays a role in the hepatotoxicity of acetaminophen. There has been extensive research into the CYP 450 genes and enzymes, and there are extensive references regarding the CYP 450 enzymes and xenobiotic metabolism [24, 26, 28, 29].

16.4.13 Single-Nucleotide Polymorphisms

Where there are genes, there are gene mutations. These mutations code for altered proteins with varying structures and activities. A common form of gene mutation is the single nucleotide polymorphism (SNP), in which a single nucleotide in a gene is changed, which may result in altered enzyme function. There are extensive publications on the effects of these polymorphisms on disease patterns and susceptibility and drug metabolism [30, 31]. There are more than 6000 review articles in the PubMed database detailing polymorphisms and their clinical effects.

In summary, if a healthy biologic system depends on the normal function of its enzyme systems, mutated genes and altered enzymes may have adverse effects on health. These consequences may vary from inconsequential to devastating. Perhaps nowhere else in the human body is the problem with mutated genes and altered enzymes more prevalent than in the liver's biotransformation enzyme systems, which critically impact xenobiotic transformation. Also important to understand is that while the biotransformation systems in the liver are vast, they are not infinite. If our purpose is to create health, the focus should be on feeding the system substances that are nutrients, not xenobiotics, and allowing the pathways in the liver to function as efficiently as possible. This requires optimizing nutrient intake and minimizing exposure to unnecessary xenobiotics. Improving the function of Phase II biotransformation in an individual patient should serve to eliminate, or to ameliorate the adverse health effects of many harmful xenobiotics.

16.4.14 Bile and the Biliary System

Bile is secreted from each hepatocyte into the bile canaliculus through a secretory process requiring energy [13]. Figure 16.5 shows a bile canaliculus as it travels along

adjacent hepatocytes on its way to the bile ductule in the portal tract. The bile ductules merge into the bile duct system, which transports bile out of the liver. Bile then flows down the common bile duct and through the sphincter of Oddi into the second part of the duodenum, where it mixes with intestinal content and begins its multifaceted function.

When there has not been a recent meal, the sphincter of Oddi is tightly closed, and the bile is diverted into the gallbladder. However, the gallbladder is more than a simple storage compartment. It concentrates bile and performs other important functions. When food is eaten, hormones, including cholecystokinin (CCK), are released, which cause gallbladder contraction, relaxation of the sphincter of Oddi, and a bolus of bile is released into the duodenum.

Bile is a micellar liquid. This means that the lipids/fats (cholesterol, phospholipids) and proteins secreted by the hepatocytes, when they reach a certain concentration in the bile, spontaneously form into round or cylindrical transport structures, which are carried in the ionic transport solution of the bile into the duodenum. Some molecules are carried in the micellar component of bile, some in the aqueous or liquid component. Bile contains bile acids which are essential to normal fat digestion, and have other metabolic properties. Bile is a potent antioxidant, and carries products from hepatic biotransformation out of the liver [32].

16.4.15 Small Intestine

The small and large intestines can be seen as the main digestive organs of the body (Fig. 16.6). The small intestine includes the duodenum, jejunum and ileum for a combined length of about 25 feet. The large intestine or colon is about 5 feet long. In the small intestine, proteins, carbohydrates, fats, vitamins, minerals and trace elements are processed, and the products of digestion are absorbed through the intestinal wall.

The inner lining of the small intestine contains circular folds called plicae, the surface of which is studded with leaf-or-finger like projections called villi. Enterocytes, the absorptive cells in the small intestine, make up 90% of the cells lining the villi [33]. The apical surface of each enterocyte faces the intestinal lumen and is itself further folded into microscopic tubular structures called microvilli. Because of the plicae, villi and microvilli, the absorptive surface of the small intestine which is exposed to food and other ingested material is vastly increased - about the size of a tennis court in an average adult.

Considering the large number and varied types of ingested substances presented to the lining of the small intestine, and the large surface area involved, the small intestine performs a monumental task of identifying toxins and pathogens, digesting nutrients, maintaining the barrier function of

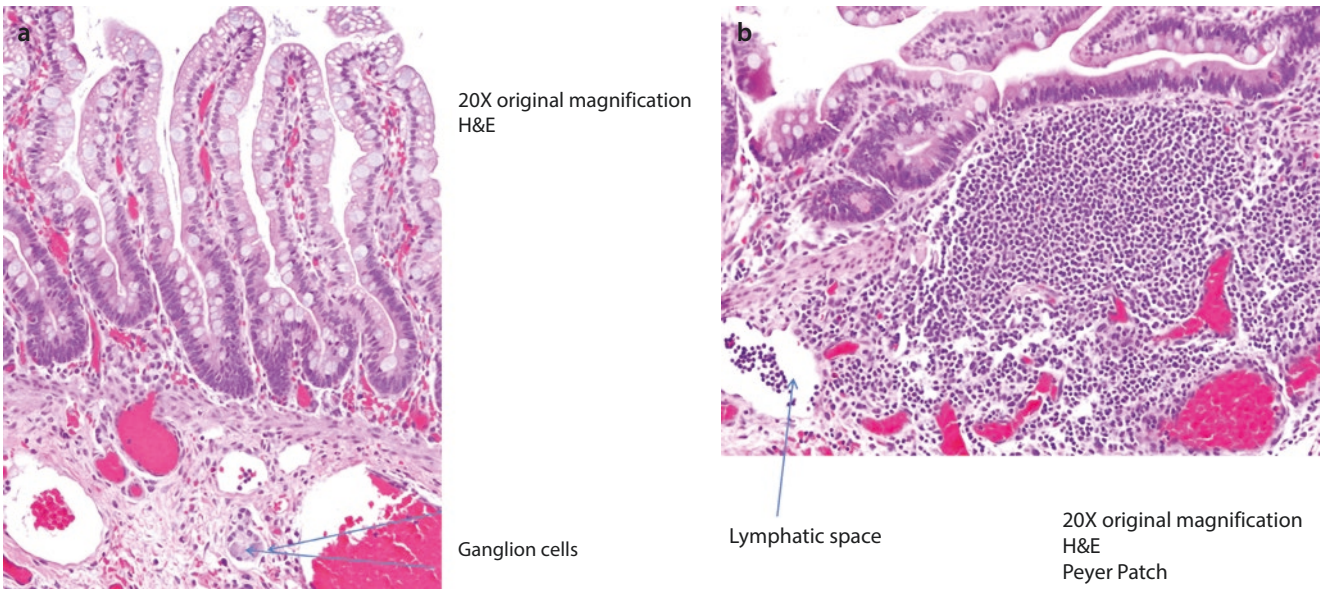

Fig. 16.6 Aspects of small intestine lining. (**a**) Photomicrograph of villi lining the mucosal surface of the small intestine. The predominant cell type is the enterocyte, through which nutrients and xenobiotics pass. Approximate surface area of the small intestinal lining in an adult is that of a tennis court, indicating the immense task of the enterocytes in distinguishing what should and should not be allowed to enter the submucosal space, and hence the portal circulation. Everything swallowed passes through the stomach into the small intestinal lumen, goes through processes of digestion, interacts with microbiome, and is sorted and evaluated, to determine if it will be allowed into the body or not. (**b**) Photomicrograph of submucosal lymphoid tissue known as a Peyer's patch, part of the GALT (gut-associated lymphoid tissue). Note lymphatic channels, and the capillaries which lead into the portal venous drainage. Fibers of the extensive enteric nervous system (the largest concentration of nervous tissue outside the central nervous system, and so called the "second brain" by some) are not visible in this exposure. Enteric endocrine cells (EEC), part of the intestinal lining, are likewise not specifically distinguished. (Courtesy of Beverly B. Rogers MD, Emory University School of Medicine)

the intestinal wall, and choosing which substances to allow to pass into the portal circulation.

16.4.16 Microbiome/Metabolome

After partially digested food from the stomach combines with bile and pancreatic secretions in the second part of the duodenum, it then passes into the jejunum and encounters the microbiome. In an average adult, the microbiome is four to five pounds of microorganisms which live in the lumen of the small and large intestines [34–37]. The microbiome begins to form immediately after birth. An infant's first stools are meconium, which is essentially digested amniotic fluid; cultures taken of meconium in healthy infants are sterile. Within a few days after delivery, microorganisms can be grown in culture. These microorganisms originate from the breast, skin, and secretions from the birth canal. Breast feeding promotes growth of *Bifidobacteria*, which have been associated with the healthy nature of stool flora in infants [38].

Bifidobacteria are well-known to be one of the more common probiotic species in the microbiome [38]. In adults, if the microbiome consists of healthy probiotic bacteria, such as *Lactobacillus*, *Bifidobacteria*, and others, this contributes significantly to healthy intestinal function and thus to the overall health of the individual. The microbiome assists in nutrient metabolism, protection against pathogens, processing of antigens and presenting them to the individual's immune system, processing of xenobiotics, and maintenance of a healthy barrier function of the intestinal wall [35]. However, if the constituents of the microbiome are pathogenic, the normal function of the microbiome is altered. The composition of the microbiome is affected by diet, antibiotics, stress, and other factors.

The term "Metabolome" refers to the multiple metabolic processes associated with the microbiome. There are more than 3000 articles referencing the metabolome, the first of which appeared in 2000 [39].

16.4.17 Enteric Nervous System

An important part of overall intestinal function is nerve cells in the wall of the small intestine forming a separate and intricate enteric nervous system (Fig. 16.7). There are multiple neuron types in multiple locations. These neurons communicate from one part of the intestine to another and back and forth with the central and autonomic nervous systems. There is bidirectional information flow between the ENS and the CNS and between the ENS and the sympathetic prevertebral ganglia [11, 12].

Sensory distress from the enteric nervous system can lead to symptoms such as nausea, bloating and pain. But most of the sensory signals from the intestine are not consciously perceived. The enteric nervous system has been called the second brain [40] because of its many functions and its vast numbers of neurons. There are more neurons in the enteric nervous system than anywhere else in the body except the central ner-

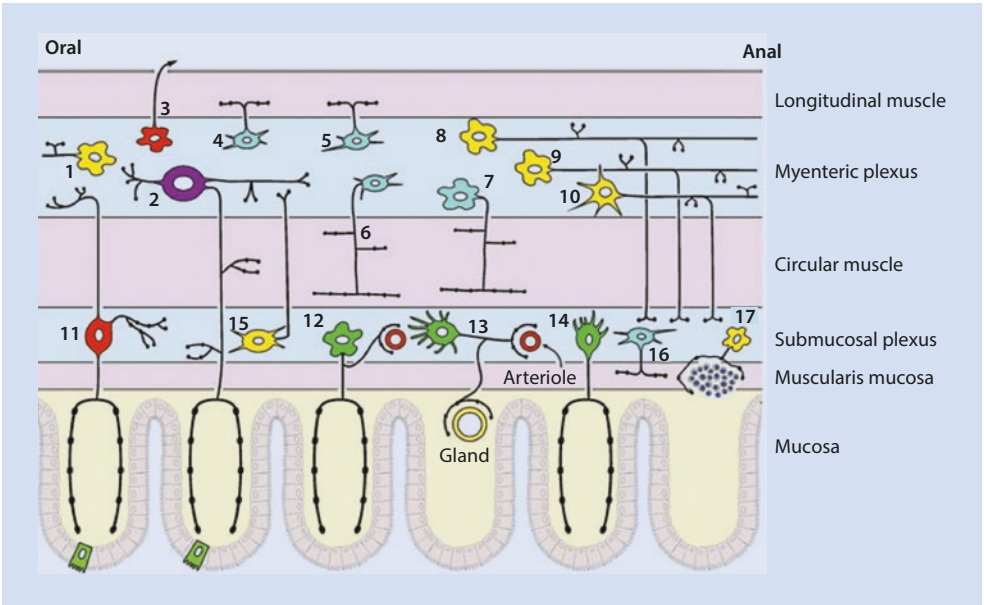

Fig. 16.7 Neurons found in small intestine defined by function, cell body morphology, chemistry, neurotransmitters, and projections to targets. Neuron types: (1) ascending interneurons; (2) myenteric intrinsic primary afferent neurons (IPANs); (3) intestinofugal neurons; (4) excitatory longitudinal muscle motor neurons; (5) inhibitory longitudinal muscle motor neurons; (6) excitatory circular muscle motor neurons; (7) inhibitory circular muscle motor neurons; (8) descending interneurons (local reflex); (9) descending interneurons (secretomotor and motility reflex); (10) descending interneurons (migrating myoelectric complex); (11) submucosal IPANs; (12) non-cholinergic secretomotor/vasodilator neurons; (13) cholinergic secretomotor/vasodilator neuron; (14) cholinergic secretomotor (non-vasodilator) neurons; (15) uni-axonal neurons projecting to the myenteric plexus; (16) motor neuron to the muscularis mucosa; (17) innervation of Peyer's patches not illustrated, motor neurons to enteroendocrine cells. (Adapted from Furness [51]. With permission from Wiley)

vous system. A number of commonly used phrases reflect this plentiful innervation of the GI tract, and its function in interacting with the central and autonomic nervous systems: "I knew it in my gut," "I had a gut instinct," or "the bowels of compassion."

16.4.18 Gut-Associated Lymphoid Tissue

The small intestine has the job of sorting out whether molecules presented to its lining cells are friend or foe, as everything ingested is not an ideal nutrient. Some substances can trigger allergic reactions while some are frankly toxic. Some molecules may be a known nutrient, but trigger the immune system to develop an autoimmune disease, the most well-known being celiac disease and the reaction to gluten/gliadin proteins [41].

The lining of the small intestine serves as a barrier between the outside world (ingested substances) and the body. This is called the intestinal barrier function, or the intestinal firewall [42]. Sometimes the function of the lining of the small intestine in forming a barrier to the outside world is compromised in various ways. Molecules may translocate or leak through the mucosal membrane by alternate pathways and can end up in the intercellular space below the mucosal lining enterocytes. This leads to increased intestinal permeability (referred to by some as "leaky gut") [43].

When non-nutrient molecules pass through the intestinal lining, the gut-associated lymphoid (GALT) system is stimulated. In the small intestine, GALT resides throughout the intestinal wall in vast numbers of microscopic collections of lymphoid tissue. In the distal small intestine and colon, these cell clusters occur in larger structures called Peyer's patches.

16.4.19 Enteric Endocrine Cells

There are more hormones produced in specialized cells of the small intestine than in any other organ in the body [44, 45]. Hormones are messenger molecules that convey various messages between cells, between different parts of the small intestine, and between the small intestine and other organs.

16.4.20 Terminal Ileum

The last 6 inches of the small intestine are structurally different from the rest. This segment is called the terminal ileum. Vitamin B12 is absorbed at this location [46]. In this segment, about 95% of the bile, which has remained inside the intestinal lumen to perform its functions, is reabsorbed and returned to the liver through the portal circulation. This absorption and recirculation of bile was the origin of the name "entero-hepatic circulation".

16.4.21 Large Intestine

The large intestine, or colon, begins in the right lower abdomen in a bulging pouch called the cecum. The terminal ileum empties into the cecum through the ileocecal valve (IC). The structure of the IC is such that it prevents reflux of contents from the cecum back into the ileum. The colon is approximately 5 feet long, and digestion and nutrient absorption are essentially complete by the time the intestinal contents enter the cecum. There is a vibrant microbiome in the colon [47, 48], and no doubt there are many metabolic functions yet to be clarified. One main role of the colon is reabsorption of water and electrolytes, preparing the stool to be passed from the body through the anus.

16.5 Conclusion

Based on the structure and function of the EHC, the ingestion of proper nutrients, possessing a healthy microbiome, maintaining an intact intestinal barrier function, and keeping exposure to xenobiotics to a minimum, the whole EHC system will function as it was designed. However, if the microbiome is unhealthy, if the intestinal barrier function allows toxic molecules to be taken up, or if there are insufficient nutrients or an overload of xenobiotics, the system will not function well. This is a reasonable place to begin in patient care. Using this paradigm and approach, patient care becomes conceptually simple: restore a healthy microbiome, restore a healthy intestinal barrier function, ensure delivery of proper and optimal amounts of nutrients, take into account biochemical individuality, and minimize harmful xenobiotics. The goal becomes identifying ways in which function deviates from this norm and taking steps to restore normal function. This is a vastly different approach from waiting until an identifiable disease develops and is diagnosed, then treating that disease with medication and/or surgery. In many cases the approach discussed above, based on correcting altered function, deals with the problem long before it forms.

Integrative nutritional care use is the closest approach to returning to the roots of human physiology and biochemistry and allowing these principles, along with patients' needs, to guide practice. In this approach, nutritional principles are applied first, along with other principles of a healthy body. Other healthcare disciplines are included in the treatment process as they are found to be useful; none are excluded. The conversations may include naturopaths, chiropractors, herbalists, nutritionists, homeopaths, acupuncturists – anyone who seems to have something to offer. At times, pharmaceuticals are needed. From the author's observation, integrative nutritional therapy is not just a new buzz-word or catch-phrase. It is not a new discipline, to be replaced at some point by another. It represents the closest paradigm found leading to understanding the principles of human physiology and allowing the use of nutrition to emerge from

that awareness. Integrative and functional nutrition properly applied leaves room for any approach, any discipline that has something to offer. With knowledgeable guidance and patient motivation, an immense amount can be accomplished.

» "Nutritional genomics refers to the application of "omics" technologies, together with systems biology and bioinformatics tools, to understand how nutrients interact with the flow of genetic information to impact various health outcomes" [1]. Nutritional genomics is an umbrella term that encompasses two distinct but related fields: nutrigenomics and nutrigenetics. Nutrigenomics may be defined as the measurable effect of nutrients on the genome, proteome, microbiome and metabolome. Thus, the use of laboratory measures such as organic acids, amino acids, homocysteine, etc. may serve as an indicator of whether a gene is functioning or impaired due to a SNP, and to what degree. This clinical data may then be used to develop a personalized nutrition plan to influence the biochemical pathways in which the SNP interacts. Nutrigenetics is similar as it also explores the measurable interactions of nutrients on the genome, however, nutrigenetics is focused on the measurable interactions between diet and *disease risk* and which dietary interventions influence intervention outcomes. This may help predict how a patient may respond to a dietary intervention in terms of controlling or exacerbating disease risk. It is therefore instrumental in the design of personalized nutrition plans to ameliorate symptoms or in the prevention of the development of various disease types.

Nutrigenetics is focused on genetic variation and disease prediction or the way that diet influences the risk of developing a disease. Nutrigenetics is most often practiced by geneticists and genetic counselors who are skilled in computational statistics. Remember, this is *disease prediction*. Nutrigenomics is focused on how nutrients affect the genome and the biochemistry we can measure related to those lifestyle choices. Measurement in this case is typically through metabolomics and microbiome analyses. Due to the reliance on metabolomics for validation, advanced nutrition professionals are the primary nutrigenomics practitioners. These are two distinct fields under one large umbrella. Epigenetics intermingles easily through both fields, making the scope a bit more challenging to decipher.

In these next sections, we will discover the salient genetics associated with several conditions. Some conditions and interventions will be strictly nutrigenetic in nature while others are more nutrigenomic. There will be some overlap as that is the nature of the field. We will dive deeply into the nutritional genomics and epigenetics of cardiometabolic disease; neurodegenerative diseases like Alzheimer's disease and Parkinson's disease; common psychiatric conditions such as depression, anxiety, schizophrenia and bipolar disorder; understand the genomics of irritable bowel disease, mitochondrial insufficiency, cancer and nutrient-related autoimmune diseases followed by an introduction to pharmacogenomics. We will elucidate the effect that stress has on methylation and the epigenome and discuss how common toxic exposures can influence methylation. Remember, hypermethylation silences gene expression while hypomethylation activates it, thus in essence, hypomethylating means to turn on the gene, while hypermethylation will typically turn it off. The goal is to have proper methylation, not over or undermethylation. This chapter is an overview of the topics and is not an exhaustive review.

17.1 What Is Epigenetics?

The term epigenetics was originally coined by Waddington in 1942. It was derived from the Greek word "epigenesis," which described the influence of genetic processes on development [2, 3]. Modern day epigenetics is the study of gene expression through histone or methyl modulation along with RNA silencing rather than the alteration of the genetic code itself. Epigenes are additional instruction layered on top of our inherited genetic code (A, T, C, G, U); this additional instruction is known as the epigenome. If we think of the genetic code as the manuscript, the epigenetic information could be viewed as the highlighted or tagged sections. These "tags" or markers indicate to the instructional processors that something is either important or that it can be ignored.This is the science that turns "on" or "off" the genes, which can result in both positive and negative outcomes.

There are a multitude of "tags" that guide the genomic processors. Some are methyl groups, others are histone modifiers, and some even modify RNA, one of the processors! These tags work together to either increase or restrict access to the genome, therefore controlling the expression of the proteins found within the genome. The really interesting part about these tags is that they are not corrected like our genetic code. These tags or markers can change based on our lifestyle, experiences, diet, exercise habits, and exposure to chemicals. This fluidity allows the epigenome to "learn" and adapt to the current environmental circumstances. These epigenetic markers can even survive what is called global DNA demethylation, or the wiping clean of epigenetic markers from the gametes when a zygote is formed. Interestingly, there is a process called imprinting whereby one of the parent's genes is "dominant" and silences the other allele. These imprinted genes keep their epigenetic tags, even through global demethylation. These are the tags that survive from generation to generation and influence genetic expression. As the new embryo forms, other epigenetic tags physically record each cell's experiences on the genome. In this recording or writing stage, the epigenome ultimately stabilizes gene expression allowing for proper embryonic development [4].

Maternal diet, smoking status, mental state, and social environment can do one of two things. This environmental information can hypomethylate CpG islands, which in essence turns on the gene, or it can result in RNA silencing, thus turning off the gene [4]. This means that the trauma that your great grandmother experienced at the turn of the twentieth century could potentially increase your risk of developing a mental illness, such as depression. Fathers also have epigenetic transfer as well, thus, it also means that your

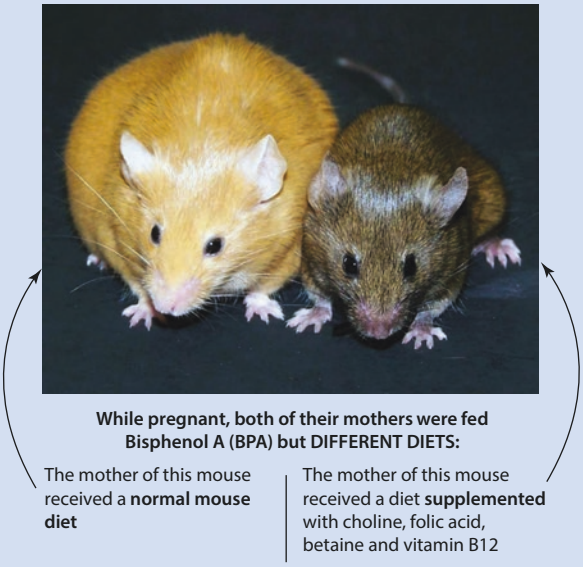
"health-nut" father could also confer more favorable cancer and cardiovascular epigenetics [5].

There are three major systems that control epigenetics including DNA methylation, histone modification, and non-coding RNA (ncRNA)-associated gene silencing [4]. There are also less well-studied processes such as acetylation and ubiquitination. In addition to these processes, the "systems" are also modifiable. For example, histone proteins are responsible for packaging DNA via chromatin complexes into dense chromosomes. Histone structures may be modified by acetylation of lysine residues, methylation of lysine and arginine residues, phosphorylation of serine and threonine residues, ubiquitination of lysine residues on histone tails, sumoylation, and ADP ribosylation. Histone acetyltransferases (HATs) add acetyl groups to lysine residues on histone tails, whereas histone deacetylases (HDACs) can remove the acetyl groups [4, 6, 7].

DNA methylation typically occurs at CpG islands, which are most commonly found in gene promoter regions [6]. It is at this CpG island that DNA methyltransferases (DNMTs) coordinate the addition of a methyl group to the 5-carbon position of the cytosine residues where it regulates transcription. DNMT1 exclusively maintains normal methylation by exact duplication of DNA between cell generations. DNMT2, on the other hand, is responsible for methylation within embryonic stem cells. Methylation has also recently been discovered to occur in non-CpG cytosines within undifferentiated stem cells [4, 7–9]. Methylation is important as not all genes are expressed at all times. *In fact, most are repressed.* Methylation is an epigenetic means of keeping genes suppressed until they are needed. Remember, methylation, especially hypermethylation, silences gene expression. Pause and consider for a moment the use of methylated vitamins and what implications this may have on DNA expression. Further, methylation is important for determining chromosomal replication timing. During hypomethylation there is late-replication, which may be demethylated slowly during cell division. Hypermethylation, on the other hand, leads to much earlier replication during S phase. Those hypermethylated genes are typically repackaged with acetylated histones. Hypomethylation will cause the building of nucleosomes that contain deacetylated histones [9]. In this way, methylation may control the "turning off" of genes.

Lastly, small non-coding RNA molecules (MicroRNAs) are a range of molecules that also help to control the expression and function of genes. They are non-coding RNAs that regulate gene expression post-transcriptionally or after the protein has been processed by the ribosome. Typically, they repress protein production by altering the capabilities of messenger RNA and by a process called translational silencing [10]. In this way, they are able to repress gene function and expression. MicroRNAs are accountable for targeting approximately 30% of genes and can influence tumor suppression, apoptosis, cellular proliferation, and cell movement [6].

Agouti mice illustrate how nutrition may modify phenotypic expression, epigenetic expression and disease risk outcome. Maternal dietary differences in methyl (CH_3) intake dictates the presence of a yellow hair color either as a band within primarily brown hair in wild-type mice, or as fully yellow hair in those with mothers who had decreased methylation. This is related to the agouti viable yellow (Avy) gene. This phenotype is accompanied by obesity and is a result of paracrine signaling issues resulting in hyperphagia in mice pups. The consequence of this epigene is that the mice expressing the aberrant agouti gene are more likely to develop diabetes and cancer later in life. The difference between pups expressing the wild-type genetics versus the polymorphism is the overmethylation status allowing for suppression of the *agouti* gene. To further influence the expression of this gene, supplementation with choline, vitamin B12, and folate both prior to and during pregnancy repress *agouti* expression [6, 11, 12] (Fig. 17.1).



While pregnant, both of their mothers were fed Bisphenol A (BPA) but DIFFERENT DIETS:
The mother of this mouse received a **normal mouse diet**
The mother of this mouse received a diet **supplemented** with choline, folic acid, betaine and vitamin B12

Fig 17.1 These two mice are genetically identical and of the same age. The larger yellow obese Agouti mouse on the left received a diet without methyl nutrients. The smaller brown healthy Agouti mouse on the right received a diet with methyl nutrients (choline, folic acid, betaine and B12). Both mice were fed BPA in each diet. In the laboratory, BPA appears to reduce methylation of the agouti gene. With the mother fed the regular (BPA-modified) diet, the pups were more likely to be yellow and obese and more prone to develop cancer and diabetes. When the mothers were fed the BPA-modified diet plus methyl nutrients, the pups were more likely to be born healthy and brown, and they were of ideal weight. The methyl nutrient supplementation counteracted the negative effects of the exposure. (Adapted from Jirtle R, Dolinoy D. Agouti Mice. Another classic example of the influence of nutrition on epigenetic expression is the *Dutch Hunger Winter Study*. This study looked at a cohort of people conceived during a famine that occurred over 6 months during the last winter of World War II (1944–1945). During this time, the caloric intake decreased from approximately 1400 kilocalories in October

1944 to less than 1000 kilocalories towards the end of November 1944. Caloric intake further declined at the peak of the famine to 400–800 kilocalories from December 1944 to April 1945. Despite the plummeting amounts of kilocalories during this time, the proportion of fats, carbohydrates, and proteins remained the same [13–15]. The study found a positive correlation between famine, calorie restriction and obesity in the offspring of women pregnant during this time. This association was further correlated to obesity-related diseases in adulthood such as atherosclerosis, hyperlipidemia, coronary artery diseases, and increased risk of cardiovascular mortality [13–15]. As a segue into obesity and obesity-related disorders, we will explore specific epigenetic influences and single nucleotide polymorphisms (SNPs) associated with cardiometabolic disease.

17.1.1 The Epigenetics of Cardiometabolic Disease

Cardiometabolic disease encompasses a cluster of disease characteristics including atherosclerosis, dyslipidemia, diabetes mellitus type 2 (DM2), hypertension (HTN), increased waist circumference and obesity [16]. All of the aforementioned conditions have genetic etiologies that can increase the risk or prevalence of the disease in affected individuals.

To begin, let us look closely at genetics that increase the risk for cardiovascular disease (CVD). Apolipoprotein E (APOε) is a cholesterol carrier that assists in lipid transport [17]. It does so by merging with endogenous lipids to form lipoproteins that are responsible for restructuring other lipids and cholesterol. These lipoproteins also circulate these lipids in the bloodstream. The three isoforms of APOε are APOε2, APOε3, and APOε4. The APOε3 isoform is considered to be the neutral genotype and confers no additional CVD risk. However, the ε2/ε2 variation is associated with familial hypercholesterolemia, or genetically related high cholesterol [18]. Dysbetalipoproteinemia is a rare familial dyslipidemia characterized by approximately equally elevated serum cholesterol and triglyceride levels due to accumulated remnant lipoproteins in apolipoprotein ε2/ε2 homozygotes [18]. This genotype is very rare with the frequency in European ethnicity at 0.3%, African American ethnicity at 0.4%, and Asian ethnicity at 0.2% as compared to the ε3/ε3 genotype with 57.4%, 41.7% and 74.6%, respectively [19, 20]. This type of predictability is nutrigenetics and is not likely to be a candidate for epigenetic alteration. However, Yang, et al. (2007) found that for those with a single variant of APOε2, there was a 2.2-fold increased risk of myocardial infarction if there was a concurrent high saturated fat intake. They also found that for those that carry a single variation of the APOε4 gene, there was a 1.6-fold increased risk of myocardial infarction when paired with a high saturated fat diet. Compared to non-carriers, the APOε2 carriers who consumed a high saturated fat diet resulted in consistently elevated LDL cholesterol levels by (+ 17%) and carriers of the APOε4 variant had an increase of (+ 14%) [21]. This dietary intervention potentially activated these genes and increased the risk of CVD.

It has been suggested that those with the ε2/ε2 variation restrict their saturated fat intake to less than 12 g/day to prevent dysbetalipoproteinemia and myocardial infarctions [21]. However, there are further complications with suggested saturated fat intake recommendations. The apolipoprotein A2 (APOA2) gene determines the amount of saturated fat required to prevent dyslipidemia in those with DM2. Those with the CC genotype at rs5082 have an increased risk for dyslipidemia and should decrease saturated fat consumption to less than 10% [22]. The current nutritional United States Department of Agriculture (USDA) guideline already recommends the consumption of less than 10% of calories per day from saturated fats (20 grams) [23]. While this may seem auto-confirmatory, recently there is an extreme trend towards ketogenic, or very high fat diets. For those with either the ε2/ε2, ε4/ε4 or APOa2 genotypes, a high fat diet would clearly be contraindicated as it would significantly increase their risk of heart attack and cardiometabolic disease. The frequency of APO ε4/ε4 is much higher than APOε2. For European ethnicity, the frequency is 2.9%, African American ethnicity 3.6%, and Asian ethnicity is 1.0% while carriers of APOε4 are 24%, 34.1% and 15.4%, respectively [19, 20]. The Yang study reviewed carriers, thus the results are associated with having only one deleterious allele.

Hypertension is a hallmark diagnostic of cardiometabolic disease. For patients with hypertension and diabetes, treatment should be initiated when blood pressure is 140/90 mm Hg or higher, regardless of age [24]. Genomically, hypertension is related to the angiotensin-converting enzyme (ACE) and the angiotensinogen gene (AGT). Angiotensinogen, which is formed in the liver and controlled by AGT, is broken down by renin to form angiotensin I. Angiotensin II is formed from angiotensin I by ACE, which is then acted upon by the angiotensin receptor (AT1R) and ultimately converts to aldosterone. Angiotensin II regulates vasodilation and constriction, the sympathetic nervous system, antidiuretic hormone, and hormones in the adrenal glands. Aldosterone is the primary adrenal hormone for this system, as it regulates sodium retention, potassium excretion and ultimately fluid balance [25]. This is the underlying mechanism for hypertension drugs called ACE inhibitors, blocking angiotensin II production and thereby lowering aldosterone production and the above-described regulatory mechanisms. However, when there is a deletion in the ACE gene, there will be an increase in aldosterone and angiotensin II because the regulator has been removed [26]. This can result in anxiety, increased cortisol, memory problems, hypertension, and autoimmunity [27]. This imbalance in aldosterone will also alter the electrolyte balance, specifically, a decrease in sodium excretion, thus sodium retention and/or swelling and an increased excretion of potassium potentially resulting in hypokalemia [25]. Alterations in the AGT gene exacerbate the ACE deletion genotype while also carrying an inherent risk for pre-eclampsia, hypertension and insulin resistance. AGT directly increases angiotensinogen levels, thereby alter-

ing the renin-angiotensin-aldosterone system (RAAS) axis. Caproli, et al. found that almost 50% of all hypertensive cases were what they termed "salt-sensitive." They found that hypertensives carrying both the ACE and AGT polymorphisms responded favorably to a reduced sodium diet (less than 1500 mg per day). Those individuals who did not carry one or both of these polymorphisms are considered non-salt-sensitive and did not have any measurable effect when restricting sodium. This study elucidates that salt restriction is not always beneficial for all hypertensive patients [25].

Diagnostic and Testing Guidelines for Diabetes Mellitus Type 2

The diagnostic criteria for pre-DM2 consist of fasting plasma glucose (F/PG) 100 mg/dL (5.6 mmol/L) to 125 mg/dL (6.9 mmol/L) (impaired fasting glycaemia) OR 2-hour PG in the 75-g oral glucose tolerance test (OGTT) 140 mg/dL (7.8 mmol/L) to 199 mg/dL (11.0 mmol/L) (impaired glucose tolerance) OR hemoglobin A1C (A1C) 5.7–6.4%, while the diagnostics for DM2 are A1C ≥6.5% OR FPG ≥126 mg/dL (7.0 mmol/L).

Fasting is defined as no caloric intake for at least 8 hour.*OR 2-hour PG ≥200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the World Health Organization (WHO), using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water OR in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dL (11.1 mmol/L) [28].

Diabetes or dysregulated blood glucose is the other pillar of cardiometabolic disease. Type 2 diabetes (DM2) is a disease of insulin resistance, most often caused by central obesity and lack of exercise. This is considered a disease of lifestyle, thus epigenetically influenced. The idea that there may be an underlying genetic component to DM2 is appealing in many ways. Currently, the research is only suggestive of correlations rather than causations. One such example is the Transcription Factor 7 Like 2 (TCF7L2) locus. Those with the TT genotype at rs12255372 have a 67% increased risk of developing DM2. There is also preliminary evidence that this SNP could possibly increase the risk of breast cancer and aggressive prostate cancer [29]. Those with the genotype should include low glycemic index/glycemic load foods, reduce sugar consumption and limit processed grains to mediate this risk [29]. Interestingly, the global risk was not mediated in all study subjects, suggesting that the epigenome and environmental conditions were influencing the disease risk outcomes. This suggests an association between family history, genetics and disease outcomes.

Further, when considering diabetes risk associated with dyslipidemia, it is important to consider the gene Paraoxonase 1 (PON1). PON1 has both esterase and lactonase activity. The esterase enzymes assist in the catabolism of pesticides and certain pharmaceutical drugs while also protecting high and low-density lipoproteins from oxidation. Alterations in this gene could result in abnormally high levels of lipid peroxides, inflammation and compromised detoxification. The lactonase activity is specific to the catabolism of homocysteine thiolactones. When there is an increase in homocysteine, the result is an elevation of oxidizing thiolactones. When there are alterations in this gene, there is the potential for elevated levels of homocysteine and HDL-specific protein damage [30]. A specific SNP in PON1, rs662 (A) confers a higher risk of coronary heart disease and diabetes because it encodes for lower amounts of PON1 activity, thereby increasing oxidative stress and CVD-related disorders [31]. Specifically, when there are errors in PON1, HDL is oxidized, conferring a higher risk of cardiovascular disease. It has been shown that both Vitamin E supplementation and a diet higher in monounsaturated fats can help decrease both oxidized HDL and the activity of altered PON1. It should be noted that a diet high in saturated fat alone can inhibit the activity of PON1 even in the absence of genetic alteration, thus creating a functional enzyme deficiency. In this way, a diet high in saturated fats can increase the risk of both cardiometabolic disease and markers such as homocysteine [32, 33].

When presented with cardiometabolic disease, one of the most researched and used supplements is omega-3-fatty acid, often as fish oil. Typically, when we think of endothelial nitric oxide synthase (eNOS/NOS3), we are associating it with vasodilation, vascular smooth muscle relaxation via cGMP-mediated signal transduction pathway, vascular endothelial growth factor (VEGF)-induced angiogenesis in coronary vessels, and its ability to promote blood clotting via platelet activation. One intriguing hypothesis is that perhaps the mediating effects in CVD from NOS modulation depend on omega 3-fatty acid status. There is a SNP in NOS3 that determines whether increasing omega 3-fatty acids will decrease triglyceride levels in those with dyslipidemia. In rs1799983, it was found that subjects with the risk allele T (TT or GT) who had low levels of omega 3-fatty acids had 25% increases in serum triglyceride levels when compared to those with the GG genotype. This study suggested that those carrying the T allele increase their omega-3-fatty acid intake by 1.24 grams/day. Once subjects repleted with omega 3-fatty acids, their triglyceride levels normalized [34]. This may be the mechanism behind the plethora of research that indicates that a Mediterranean diet [35] or a diet high in fish like the Okinawan diet [36] confer such benefits in regards to CVD and cardiometabolic disease. It also may suggest a potential genetic component to omega-3 therapy in CVD and hypertriglyceridemia and should be a consideration in prescription/supplemental omega-3 therapy. It is also important to consider the corollary for this SNP, meaning those who do not have the risk allele and who may not be fish oil responders.

This brings us to the final pillar of cardiometabolic disease – obesity. It would be helpful for individuals and practitioners if there simply were a "fat" gene to determine whether dieting would be effective. Unfortunately, we have yet to find the genetic holy grail of obesity, but we have made some progress. Enter the fat mass and obesity gene (FTO). There has been quite an evolution of this gene and our understanding of its implications. To start, it was once a five-membered haplotype, meaning that there were five causally associated SNPs within the FTO locus that "predicted" the impact of

FTO [37]. Later, this group was revised to a three-membered haplotype, and then finally in 2015, a so-called causal variant was discovered [38]. SNP rs1421085 (C, C) confers a 1.7× increased obesity risk while the heterozygous form confers 1.3× increased obesity risk [39]. These are pretty low odds risks, and the magnitude does not exceed 4, meaning that this gene may play a minor role in obesity-related risks. This SNP disrupts the pathway for adipocyte thermogenesis involving ARID5B, IRX3, and IRX5, all regulatory genes for adipogenesis. Evidence suggests that because IRX3 binds so strongly to FTO, that other obesity-linked SNPs may be associated with IRX3 but not necessarily with FTO expression [40]. As you can see, we are merely scratching the surface. Unfortunately, we are unlikely to find a single answer to our complex obesity epidemic; instead, understanding and adjusting the epigenetics of obesity and cardiometabolic disease are far more promising. This epigenetic adjustment may include changes to diet and lifestyle, as well as optimizing methylation status.

Two conditions associated with cardiometabolic disease include polycystic ovarian syndrome (PCOS) and hemochromatosis (HFE). PCOS presents with infertility, hirsutism, polycystic ovaries, and insulin resistance, three out of five of these having considerable overlap with cardiometabolic syndrome [41]. The genomics of PCOS are heterogenous and have minimal GWAS (genome-wide associations). The SNPs that are associated with PCOS have been found only in non-obese PCOS patients, which is not the typical presentation of the disease [42]. There is, however, a sulfation gene, sulfotransferase 2A1 (SULT2A1), which may have a role in adrenal androgen excess in women with PCOS. Sulfotransferases are important for the metabolism of drugs and endogenous compounds. They convert them into more hydrophilic, water-soluble sulfate conjugates that then may be safely excreted. SULT2A1 specifically catalyzes the sulfation of steroids like DHEA and bile acids from the liver and adrenal glands. Alterations in these genes may increase the risk of PCOS by increasing endogenous levels of DHEA and/or be associated with hirsutism and insulin resistance [43].

Next is a clearly nutrigenetic condition, hemochromatosis (HFE). HFE C282Y accounts for 85% of all hemochromatosis cases. Another minor variant, HFE H63D, is responsible for the remaining 15% of cases, often with a milder presentation [44]. Hemochromatosis is an iron-overload syndrome that results in cirrhosis of the liver, diabetes, hypermelanotic pigmentation of the skin, heart disease, liver cancer, depression, and fatigue [45]. This condition can be exacerbated by hepatitis infections and it is associated with hypogonadism in males. When these genes are present, it is best to avoid excessive dosages of vitamin C as to not increase the absorption of non-heme iron. When presented with cases of liver disease, diabetes and cardiovascular disease, when the genomics does not necessarily make sense, it is important to rule out genetically inherited conditions such as HFE.

17.1.2 The Epigenetics of Psychiatric and Neurodegenerative Diseases

The gold standard of diagnostics for psychiatric diseases is the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-V. Dementia is characterized in the DSM-V; however, Alzheimer's disease (ALZ) is not specifically categorized [46]. This is a conundrum as more than half of dementia cases have ALZ as an etiology [47]. DSM-V characterizes dementia as having "multiple cognitive deficits, which include memory impairment and at least one of the following: aphasia, apraxia, agnosia or disturbance in executive functioning. Social or occupational function is also impaired. A diagnosis of dementia should not be made during the course of a delirium (a dementia and a delirium may both be diagnosed if the dementia is present at times when the delirium is not present) [46]." Interestingly, the same apolipoprotein (APOƐ) that increases the risk for cardiovascular disease (CVD) is also associated with ALZ. This raises the epigenetic question of true disease etiology: Is ALZ a disease of environmental exposures and lifestyle choices rather than Mendelian genetics? Many would argue yes, and some have even gone so far as to rename ALZ type 3 diabetes [48]. When we consider inheritable diseases, we should also remember that families often experience identical environmental influences. Therefore, it is challenging to decipher true genetic etiology and risk when the epigenome greatly confounds such concepts.

Let us consider the nutrigenetics, or Mendelian genetics, that are associated with ALZ. As with cardiovascular disease (CVD), the ε3 variant in APOε is considered to be neutral with an odds ratio of 1 [49]. The ε2/ε2 genotype is actually protective of ALZ with approximately a 0.5 (0.22–1.1) odds ratio [49]. While the frequency of this ε2/ε2 genotype is quite rare and protective for ALZ, it also increases the risk for beta dyslipidemia. This is a case where the phenotype would present with CVD and not ALZ. However, the more common genotype, ε4, connects the two conditions clearly. Carrying one variant of ε4 is associated with approximately 3.4 (3–3.8) times increased odds of developing ALZ. Carrying two copies of the ε4 variant exponentially increases the risk resulting in an approximately 12.9 (10.2–16.2) times increased odds risk of developing ALZ in populations of European ancestry [49]. Thus, for those that carry even one of the ε4 variants, there is an increased risk for both CVD and ALZ. Further associating CVD with ALZ, Corneveaux et al. also found a consistent relationship with ALZ disease risk predictability to polymorphisms in angiotensin-converting enzyme (ACE), one of the hypertension-related SNPs [49]. There are many other genetic factors that play into the overall risk of developing ALZ that should also be considered outside of APOe, ACE, and CVD genetics. Studies have identified certain GWAS SNPs that are associated with both early and late onset ALZ, as well as many other regulating factors such as amyloid precursor protein (APP), Presenilin 1(PSEN1) and Presenilin 2 (PSEN2) [50]. The jury is still out on the etiology of ALZ

and CVD; however, dietary and lifestyle choices clearly play an epigenetic role in the development of both diseases [49]

The DSM-V diagnostic criteria for generalized anxiety disorder (GAD) include the following: "The presence of excessive anxiety and worry about a variety of topics, events, or activities; the worry is experienced as very challenging to control; the anxiety and worry are associated with at least three of the following physical or cognitive symptoms (in children, only one symptom is necessary for a diagnosis of GAD): edginess or restlessness, tiring easily; more fatigued than usual; impaired concentration or feeling as though the mind goes blank; irritability (which may or may not be observable to others); increased muscle aches or soreness; difficulty sleeping (due to trouble falling asleep or staying asleep, restlessness at night, or unsatisfying sleep) [46]."

Generalized anxiety disorder (GAD) affects approximately 22% of the population, and more often in females than males [51]. With GAD affecting approximately one quarter of the population, there are epigenetic lifestyle factors and genomic alterations that need to be addressed.

First, our modern lifestyle prizes working excessive hours, typically away from home, while also trying to manage the basics of life, family, and household. Many work so many hours that they compromise their sleeping habits (impaired cortisol regulation), not to mention their diet (obesity, nutrient deficiency) and activities outdoors (vitamin D deficiency). Each of these factors are individually enough to alter the epigenetic activation of disease. In ▶ Chap. 18, the complex system of methylation is detailed. In brief, methylation is the process of moving methyl groups from one bio-molecule to the next, ultimately functioning in the regulatory capacity for everything from DNA synthesis, expression and modulation to other complex systems such as detoxification. Many of our modern diseases can be connected to alterations in this complex system due to the implications of regulating gene expression [52]. GAD, panic disorder and milder presentations of anxiety are not exceptions.

There is an enzyme called phenylethanolamine N-methyltransferase (PNMT) (notice the word, methyltransferase; it transfers a methyl group from one molecule to another). In this case, PNMT specifically converts norepinephrine to epinephrine [53]. In more common terms, these bio-molecules are called noradrenaline and adrenaline. Chronic activation of this enzyme increases adrenaline and results in anxiety, insomnia, and ultimately adrenal fatigue [53]. The cofactor for this particular enzyme is the universal methyl donor, s-adenosyl-methyltransferase (SAM) [54]. When SAM releases its methyl group, it is first converted to s-adenosyl-homocysteine and ultimately into homocysteine, an inflammatory amino acid metabolite associated with neuroinflammation and CVD. Therefore, chronic stress can result in anxiety, elevated levels of homocysteine, CVD and a depletion of beneficial methyl donors, thereby increasing overall disease risk. This enzyme provides the biological basis for the connection between chronic stress and disease. Mind-body techniques such as yoga, tai-chi, meditation, gentle exercise, sound therapy and prayer are helpful strategies to reduce daily stress [55].

Delving a bit deeper into the genetics and epigenetics of anxiety, there are two major enzymes (genes) that can control either catecholamine regulation (dopamine, epinephrine and norepinephrine) or other excitatory neurotransmitters like glutamate. For more detailed information on catecholamine synthesis, please refer to ▶ Chap. 18. The regulatory enzyme for the catecholamines is called catechol-o-methyltransferase (COMT) (another methyl-transferase). COMT transfers methyl groups from SAM to the catecholamines dopamine, epinephrine and norepinephrine while assisting in their degradation (◘ Fig. 17.1) [56]. COMT also transfers other methyl groups, like those found in foods like green tea, citrus (quercetin), and potatoes, along with the hormone catechol estrogen [57]. The issue with this being a methyltransferase is that it is dependent on the flow of methyl groups generated in one-carbon metabolism, and recycled or processed in methylation pathways. Having both too little SAM and too much s-adenosyl homocysteine (SAH) can create inhibition or downregulation of enzymatic activity resulting in an increase of catechols. This can be independent of genetic alteration creating a functional inhibition of this enzyme [58]. This enzyme has broader applications and connects neurotransmitter regulation, estrogen metabolism and diet. Like most nutrigenomic enzymes, this one is dependent on a nutrient cofactor, or "catalyst" that is required for the enzyme to function properly (note: this is not a true catalyst in chemical terms as the catalyst is not always consumed, rather in these cases, we are describing a circumstance where the substrate is being converted to a product and this reaction requires a cofactor). The cofactor for COMT is the incredibly important mineral, magnesium [59]. In addition to serving as a cofactor for COMT, magnesium is also a cofactor for 300 other enzymatic processes in the body [60, 61]. The phenotype for this type of anxiety typically excludes panic attacks, but there is a ruminating presentation of anxiety and an increased risk for insomnia [62] and palpitations [63]. Anecdotally, those with COMT inhibition (functional or SNPs) typically have "type A" personalities due to increased dopamine and epinephrine levels, are often successful and may or may not have disordered sleep patterns.

Magnesium deficiency can be the result of many things, including downregulation of the COMT enzymes. If you consider basic sciences and relate that all enzymes have a substrate, a catalyst and a product, when there is an upregulation of this pathway, there will be a depletion of the substrate and catalyst with an increase in the product. If there is a downregulation, there is either a catalyst deficiency (nutrient deficiency) or a SNP. In the case of upregulation, COMT depletes methyl donors by moving them too swiftly away from the catecholamines, thus ultimately decreasing these levels while simultaneously decreasing its catalyst cofactor, magnesium. This may present with fatigue and potentially dopamine depression. To validate this on an organic acids test, the markers vanilmandelate (VMA) and homovanillate (HVA) would be decreased showing excessive breakdown. In

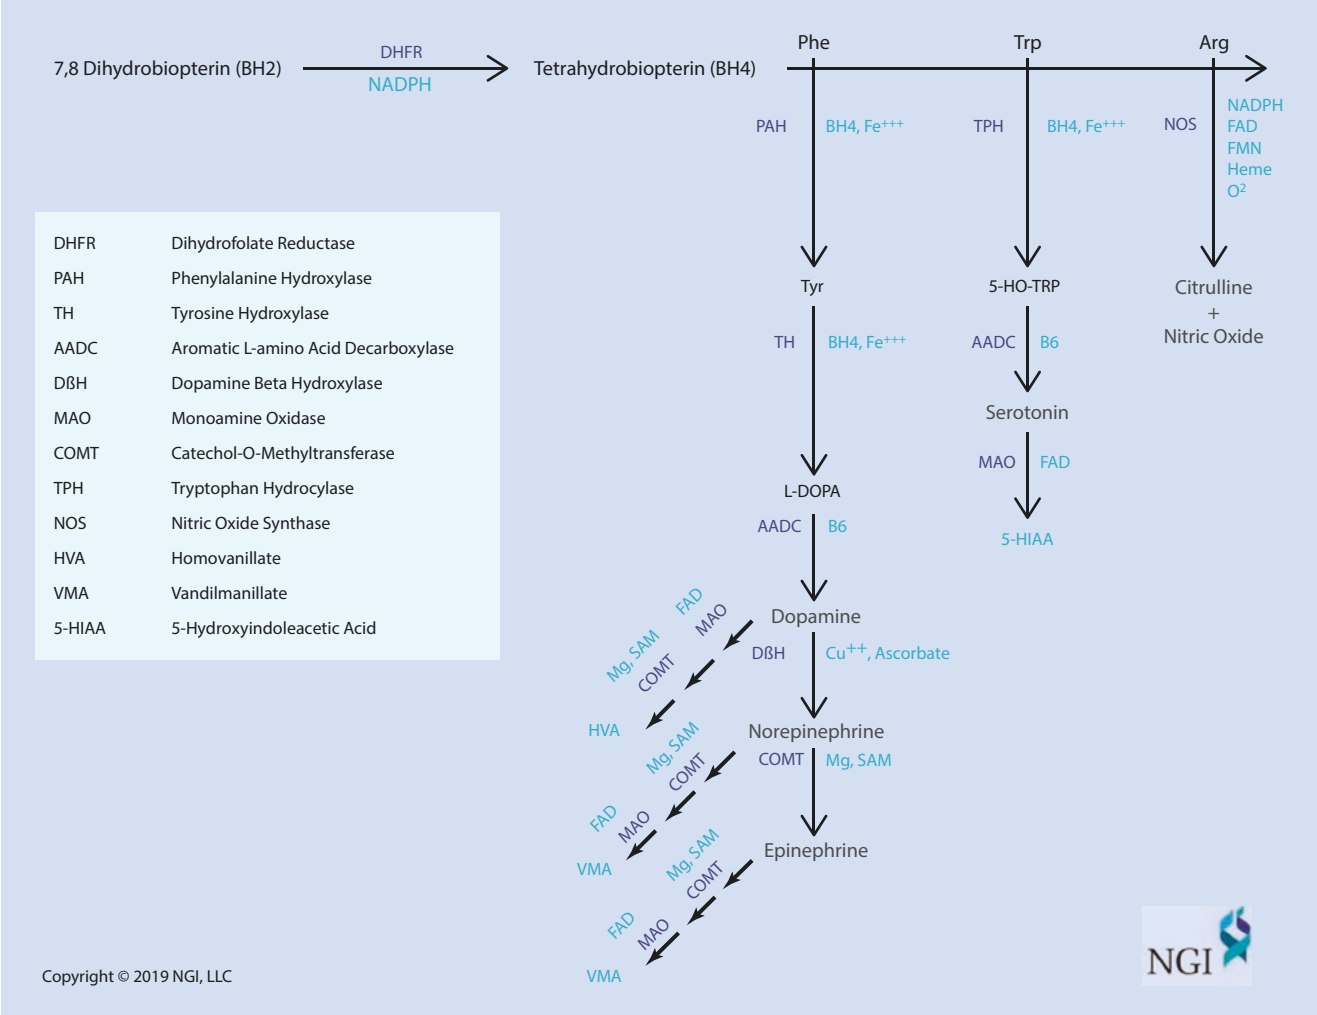

Fig. 17.2 BH4 and neurotransmitter synthesis. (Courtesy of Nutritional Genomics Institute, LLC)

downregulation, there is a "block" in the pathway, resulting in the inhibition of catecholamine breakdown, thereby resulting in increased levels of these neurotransmitters and the presentation of anxiety. The HVA/VMA pattern will be reversed in this case. If the presentation is consistent and there is a known alteration in COMT, magnesium threonate may ameliorate symptoms and anxiety. This particular form of magnesium has the potential to cross the blood-brain barrier and is considered to be a superior form for neurological conditions [64]. Interestingly, clinically, this pathway strives for homeostasis. Many patients will experience a refractory response or increased anxiety or insomnia when given magnesium. In these cases, it is important to investigate the other enzyme that also degrades these neurotransmitters, monoamine oxidase.

According to the DSM-V, panic disorder includes the following: "panic attacks must be associated with longer than 1 month of subsequent persistent worry about: (1) having another attack or consequences of the attack, or (2) significant maladaptive behavioral changes related to the attack. To make the diagnosis of panic disorder, panic attacks cannot directly or physiologically result from substance use (intoxication or withdrawal), medical conditions, or another psychiatric disorder. Other symptoms or signs may include headache, cold hands, diarrhea, insomnia, fatigue, intrusive thoughts, and ruminations." [46] (Fig. 17.2).

There is another presentation of anxiety as alluded to above. While this phenotype of anxiety can also include symptoms such as insomnia, it *includes* panic attacks associated with panic disorder. Panic attacks are associated with an enzyme that converts the excitatory neurotransmitter glutamate into the inhibitory neurotransmitter, γ-Aminobutyric acid (GABA). Not to be confused with generalized anxiety disorder, however, the name of this enzyme is glutamic acid decarboxylase 1 or GAD1. When there are alterations in these enzymes, there is a "block" in the conversion, resulting in an increase in glutamate and a decrease in GABA. This block is typically related to the limitation of the cofactor, vitamin B6 in the active form of pyridoxal-5-phosphate (P5P). To "validate" the decreased activity of this SNP, there is an organic acids marker called xanthurenate. When elevated, this is confirmation of a P5P deficiency [65].

Glutamate is found in a variety of foods, especially processed foods. Its most notorious conformation is monoso-

dium glutamate or MSG. MSG can increase glutamate levels in the brain and increase both neuronal and gastrointestinal inflammation via nuclear factor kappa-beta (NF-κB) [66]. Glutamate is also a modulator of the kynurenine pathway, which is limited by tryptophan and modulated by the nutrients pyridoxal-5-phosphate (vitamin B6), niacin (vitamin B3), iron, and magnesium. This association is consistent with the presentation of anxiety with concurrent depression as tryptophan is the precursor to serotonin. Alterations in this pathway may result in an increase in quinolinate, a neuroinflammatory metabolite responsible for modulating N-methyl-D-aspartate (NMDA) receptors in the brain. Excessive stimulation of the NMDA receptors results in neuronal inflammation and is associated with conditions like autism spectrum disorder and ALZ [67]. These GAD1 isoforms provide potential etiologies for panic disorders being genetically inherited [68]. For those having alterations in GAD1, supplementation with P5P, magnesium, niacin, and potentially iron (if deficient) can help to modulate the panic attack phenotype. If there is concurrent depression, consider also supplementing with tryptophan or 5-hydroxytryptophan.

The GAD enzyme has another interesting association. In cases where there is a homozygous alteration in the GAD enzyme, there is an increased risk for glucose dysregulation. This particular alteration results in a peculiar presentation, whereas there are moderately elevated levels of plasma blood glucose with low levels of fasting insulin. This presentation typically has the phenotype of reactive hypoglycemia, thin habitus and an erroneous diagnosis of DM2 [69]. The connection between these two clinical presentations lies in the physiology of GAD being expressed in both the brain and the beta islet cells of the pancreas [70]. To correct the discrepancy, moderate to high dosages of P5P provide an intervention to stabilize the glucose dysregulation. Interestingly, ACE inhibitors also modulate this particular mechanism, contributing to the complexity of a clinical diagnosis [71]. An ACE deletion and homozygous GAD isoform would create the phenotype of cardiometabolic disease. Clinically, this would be difficult to distinguish, perhaps other than the thin habitus. The lesson is to not make assumptions about the etiology of disease based solely on clinical presentation. The reality is often complex.Depression (major depressive disorder, MMD) is defined by the DSM-V as: "depressed mood or a loss of interest or pleasure in daily activities for more than 2 weeks; mood represents a change from the person's baseline; impaired function: social, occupational, educational; specific symptoms, at least five of these nine, present nearly every day:

1. Depressed mood or irritable most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful)
2. Decreased interest or pleasure in most activities, most of each day
3. Significant weight change (5%) or change in appetite
4. Change in sleep: Insomnia or hypersomnia
5. Change in activity: Psychomotor agitation or retardation
6. Fatigue or loss of energy
7. Guilt/worthlessness: Feelings of worthlessness or excessive or inappropriate guilt
8. Concentration: Diminished ability to think or concentrate, or more indecisiveness
9. Suicidality: Thoughts of death or suicide, or has suicide plan

DSM-V proposed (not yet adopted) anxiety symptoms that may indicate depression: irrational worry, preoccupation with unpleasant worries, trouble relaxing, feeling tense, fear that something awful might happen" [46].

Lastly, we will discuss depression. Please refer to Fig. 17.2 for additional information regarding the synthesis and catabolism of dopamine and serotonin along with specific variant information. Clinically, there are two types of depression [71]. The first and most commonly known is related to serotonin deficiency. This mechanism has spawned an entire class of pharmaceutical drugs called selective serotonin reuptake inhibitors (SSRIs). While success is found in a portion of MDD patients with SSRIs, there is a considerable portion of non-responders [72]. Clinically, serotonin deficiency-related depression encompasses feelings of worthlessness, a tendency to withdraw from social activities, lack of motivation and excessive sleeping. To validate serotonin depression, there is an organic acids marker called 5-hydroxyindoleacetic acid (5-HIAA), a serotonin catabolism metabolite. This marker will be low if there is a restriction in serotonin metabolism with concurrent suppression of the amino acid tryptophan [67]. There may also be variations in the enzymes that create serotonin, such as tryptophan hydroxylase. The cofactors for this enzyme are (tetrahydrobiopterin) BH4, P5P, riboflavin, and copper. Addressing any abnormalities found in these nutrients could potentially relieve the strain on the enzyme responsible for forming serotonin [67]. In cases such as these, consider supplementing with tryptophan, 5-hydroxytryptophan or St. John's wort. It should also be noted that in addition to the expected downregulation phenotype, there are also upregulations in the genes that regulate this pathway. Monoamine oxidase A (MAO-A) specifically regulates serotonin catabolism and is the enzyme that stimulated the class of medications known as MAOIs or monoamine oxidase inhibitors. In these cases, you may find that 5-HIAA is actually elevated along with the validation marker for riboflavin, glutaric acid [73].

The second, less frequently recognized form of depression involves dopamine deficiency. Clinically, these patients present with a decreased interest or pleasure in most activities. Often in these cases, there is an upregulation in dopamine beta hydroxylase (DβH), which converts dopamine to norepinephrine. DβH requires the cofactors of vitamin C and copper, elucidating the characteristic low copper phenotype in dopamine depression [74]. A blockage in this enzyme is associated with schizophrenia treatment outcomes as it can theoretically increase dopamine levels [75]. Dopamine can also be restricted by one of four dopamine receptors. There

may be functional blocks in these receptors due to autoantibodies or polymorphism. Acute neuropsychiatric conditions like pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) and pediatric acute-onset neuropsychiatric syndrome (PANS) are also associated with autoantibodies to dopamine receptors. In the majority of these cases, supplementing with mucuna pruriens, also known as the velvet bean, supplies a direct precursor to dopamine, L-DOPA and resolves the symptoms of dopamine depression [76].

Sometimes, there will be abnormalities in both dopamine and serotonin. If there is evidence to support this conclusion, then there may be an enzyme deficiency in aromatic L-amino acid decarboxylase (AADC). This enzyme is P5P-dependent and is responsible for both the conversion of L-DOPA to dopamine and 5-hydroxytryptophan to tryptophan. Supplemental P5P is again the correct intervention for depression. It is also possible that there are genetic abnormalities or functional blocks in both the serotonin and dopamine pathways, thus this consideration should not be disregarded. For overall support, supplementation with P5P, magnesium and riboflavin are complementary for the resolution of anxiety and depression.

17.2 The Epigenetics of Irritable Bowel Disease and Dysbiosis

For every client that has a neurological condition, there are five more that have a variation of dysbiosis, leaky gut or irritable bowel disease (IBD). In this section, we will briefly discuss dysbiosis, environmental factors such as dietary influences and probiotic use associated with dysbiosis, and the genetics of celiac disease (CD). This is not an exhaustive review and is designed as an introduction. It is important to remember that humans have a symbiotic relationship with our microflora. While it is popularly believed that our microbes outnumber us in a ratio of 10:1, these numbers have recently been recalculated to show that while there are still more microbial species than there are human, the ratio is closer to 1:1 [77]. Regardless of these ratios, the concept that we equally share the control panel with the microbiome has considerable implications on our health, disease, and longevity.

Celiac disease affects only a small percentage of the population. It is estimated that between Europeans and Americans, there is an approximate 0.5–1.26% frequency of CD [78]. CD presents with damaged epithelial cells of the intestine, malnutrition, diarrhea, anemia, osteoporosis, dermatitis herpetiformis, dental enamel hypoplasia, an increased risk of cancer and neurological symptoms such as headache, brain fog, and paresthesia [78, 79]. The etiology of this disease is an autoimmune reaction to the gluten protein found in cereal grains such as wheat, barley and rye [79]. The current guidelines for the diagnosis of CD includes: Signs and symptoms suggestive of CD, anti-transglutaminase type 2 antibody (anti-TG2) with levels typically more than 10 times the upper limit of normal and a positive confirmation test of anti-endomysium-IgA antibodies (EMA) [79]. As we begin to explore the genetic susceptibility of CD, we will encounter a condition that has recently been coined to explain the sudden rise in gluten sensitivity in the absence of CD. This new condition has been named non-celiac gluten sensitivity (NCGS), and it is associated with heterozygous alterations in the human leukocyte antigen (HLA) genes that determine CD. HLAs are a highly polymorphic gene complex that encodes for the major histocompatibility complex (MHC) proteins. These MHC proteins are primarily responsible for immune regulation and are the genes that require matching for organ transplants [80]. Alterations in these genes increase the risk of several autoimmune diseases.

About 90–95% of CD patients carry a certain genotype called HLA-DQ 2.5. When there is a homozygous mutation for this genotype, there is a 50-fold increased risk of developing CD [81]. The other remaining 5–10% of CD patients have a milder alteration in HLA-DQ 8. The presence of a homozygous alteration in this genoset results in a 17-fold increased risk of CD development [81]. In some cases, especially in NCGS, there are heterozygous alterations in these SNPs or other related SNPs that result in a genotype called HLA-DQ 2.2. Please refer to the Epigenetic SNPs chart associated with this chapter for specific details, genes and SNPs regarding HLA-DQ 2.5, HLA-DQ 8, and HLA-DQ 2.2 (see Table 17.1).

Interestingly, 40% of the general population also has alterations in these DQ genes, yet they do not develop CD. NCGS can also be present in the absence of any known genomic alteration, which complicates the suspected etiologies [81]. Dr. Stephanie Seneff proposes that this dramatic rise in NCGS and CD is associated with the relatively recent advances in biotechnology. Glyphosate is commonly known as Roundup ® and is trademarked by Bayer AG [45]. This chemical is not only a ubiquitous herbicide, but the majority of our mega crops have been genetically altered to be "Roundup-ready" or have the ability for the plant organism to survive glyphosate application, while killing the other "weeds." These genetically modified organisms (GMOs) can potentially compromise the cytochrome p450 system, result in NCGS, irritable bowel syndrome and unfavorable alterations in the microbiome as well as negatively stimulate the immune system [82]. Unfortunately, GMO wheat, corn, and soy comprise a large portion of the American diet as recommended by the USDA [83]. Here we see can clearly see the advancements in crop productivity directly impacting the epigenome and risk for CD and NCGS. These environmental conditions (i.e., how much of these foods we consume) ultimately determine if these genes are to become epigenetically activated. Remember, the presence of the genetic alteration increases the risk of the disease, but it not solely diagnostic.

This balance of the microbiota is far more important than we imagined in the age of antibiotics. Further, there is a great deal of variability in the microbiomes of individuals. We have learned that these nuances relate to health status, age, diet, microbial interactions, and even host genotype.

Fucosyltransferase 2 (FUT2) mutations, in particular, appear to be the cause of many abnormalities in the microbiome. FUT2 encodes the fucosyltransferase 2 enzyme, which determines secretor status. Secretor status allows for expression of the ABH and Lewis histo-blood group antigens in various secretions including the intestinal mucus. The presence of a particular SNP in FUT2, rs601338 (G>A) results in the non-secretor status. There is also another potential candidate SNP, rs516246 for which there has been considerable linkage to phenotypic expression. It appears that 20% of individuals who are of European descent have this non-secretor FUT2 polymorphism [84].

A 2011 study concluded that those with FUT2 polymorphisms (non-secretors) had only half of the *bifidobacterial* diversity and richness found in secretors. In particular, absence of bacterial denaturing gradient gel electrophoresis (DGGE) genotypes of species such as *Bifidobacterium adolescentis, Bifidobacterium catenulatum/pseudocatenulatum,* and *Bifidobacterium bifidum* were noted. In addition to the noted absence of beneficial bacteria, they also found that there are increased levels of potentially harmful bacteria such as *Blautia* et rel., *Dorea formicigenerans* et rel., *Ruminococcus gnavus* et rel., and *Clostridium sphenoides* et rel [84, 85]. Further, FUT2 non-secretor status also places individuals at higher risk for various diseases including Crohn's disease, ulcerative colitis, type 1 diabetes, vaginal candidiasis and urinary tract infections [84, 85]. Additionally, non-secretors have decreased carbohydrate availability in the intestine, which can cause increased risk of *Salmonella* and *C. difficile* following antibiotic treatment [84]. While more recent studies have called this relationship into question, supplementation with beneficial *bifidobacteria* can still be helpful in those with FUT2 polymorphisms.

A study that investigated Crohn's disease risk in those with FUT2 polymorphism found that mucin 2 (MUC2) might also play a role in this risk [86]. MUC2 is secreted in mucin in the colon and helps provide a barrier that excludes bacteria from the mucosal cell surface. This mechanism ultimately decreases the risk for colitis [86]. Aberrant glycosylation of MUC2 core proteins have been shown to cause spontaneous colitis in mice; thus, it appears that FUT2 negatively impacts microbial adhesion and/or the use of glycans that may lead to dysbiosis.

This association with dysbiosis was further related to the revelation that non-secretors were deficient in several pathways responsible for amino acid metabolism, but interestingly had higher metabolism rates for carbohydrates and lipids, cofactors, and vitamins and glycan biosynthesis [86]. These metabolic abnormalities can alter the integrity of the mucosal epithelium, which then alters the microbial composition. Interestingly, the decrease in the production of amino acids is often reported in those with inflammatory bowel disease (IBD). Alternatively, the metagenome shows an alternate pattern. It showed that while those with IBD had decreased amino acid biosynthesis and carbohydrate metabolism, these conditions resulted in an increased nutrient uptake. This could potentially suggest that the microbiota are compensating for the decreased availability of carbon sources. Further, a condition that results in decreased amino acids may cause a stress response in the individual and therefore the onset of autophagy of intestinal epithelial cells that may ultimately cause IBD [86]. It is important to note that these perturbations can result in sub-clinical intestinal inflammation even in apparently healthy individuals with FUT2 polymorphisms. Supplementation with zonulin tightening nutrients like zinc carnosine can be helpful in those with FUT2 associated intestinal permeability [87].

Lastly, to round out the genomic potential for IBD, specifically Crohn's disease, there is a gene called amiloride binding protein 1 (ABP1/AOC1). This gene is involved in histamine metabolism and poses an interesting intersection between diet and disease. A specific copper dependent SNP in this gene, rs1049793, is associated with an exacerbation in Crohn's disease symptoms. ABP1 is specifically responsible for the regulation of polarized epithelial cells, a mechanism that is dysregulated in IBD [88]. This effect can be compounded if there are also alterations in FUT2 and/or MUC2. It is important to assess copper and cobalamin status in these cases.

There are two mechanisms for histamine degradation, one working intracellularly and the other working via extracellular histamine degradation. Intracellular histamine metabolism is carried out by histamine methyltransferase (HNMT) while extracellular degradation occurs via another enzyme called diamine oxidase (DAO). ABP1 is one gene that encodes DAO, thus regulating extracellular histamine degradation [89]. Histamine is released in the body upon mast cell degranulation and there are four regulatory histamine receptors (H1R-H4R). H1 receptors are found throughout the body in smooth muscle, vascular endothelial cells, the heart and central nervous system. H2 receptors trigger the gastric secretion of histamine to regulate hydrochloric acid production. Less is known about H3 and H4 receptors; however, H1–H3 receptors are primarily found in the brain and H4 receptors are found in the periphery [90]. Histamine is responsible for a staggering number of biological effects, which vary based on receptor, cell location and target cell. Examples include gastric acid secretion, neurotransmitter release, smooth muscle constriction, vasodilation, tachycardia, arrhythmia, stimulation of nociceptive nerve fibers, and an increase in estrogen and endothelial permeability, which results in dysbiosis and an increase in mucus production [89].

The signs and symptoms associated with Crohn's disease include increases in *Bacteroides,* decreases in *Firmicutes* and anti-inflammatory *F. prausnitzii,* chronic diarrhea, increased smooth muscle contractions, excessive bowel mucus production, bleeding from the rectum, weight loss, and fever [91]. As evidenced, there is the potential for considerable overlap between histamine intolerance and Crohn's disease. Crohn's disease presentation and the histamine intolerance associated with the consumption of certain trigger foods appear to have a linear relationship, whereas alterations in ABP1 decrease DAO, which ultimately results in histamine intolerance and intestinal permeability [92]. There are several foods

(i.e., epigenetic activators) that are thought to be high in histamine that may need to be avoided. Examples include fermented foods, alcohol, pickled foods, mature cheeses, smoked meats, shellfish, beans, nuts, and wheat. Some foods are also considered to be histamine liberators. These include most citrus fruits, strawberries, cocoa and chocolate, nuts, papaya, beans, tomatoes, wheat germ, and additives (benzoate, sulfites, nitrites, and glutamate). There are also foods that block diamine oxidase (DAO) which can be problematic, as a block in extracellular histamine degradation would ultimately result in excessive circulating histamine. Examples include alcohol, black tea, energy drinks, green tea, and mate tea. Most fresh meats, fruits, vegetables, eggs, grains, cooking oils, herbs, and non-citrus juices are low in histamine and are non-degranulating. Other known dietary triggers for histamine intolerance may include sulfur, gluten, oxalates, salicylates, and lectin, all of which may play a role in IBD [93].

The relationships between diet, genomics, microbiota, and disease are being discovered exponentially. Once we have mastered the other "omics," there is the potential for truly precise medicine, disease modulation and nutritional intervention.

17.2.1 The Epigenetics of Nutrient-Associated Diseases

To continue with the relationship between nutrients and diseases, we will discuss the relationship between vitamin B12, vitamin D, and autoimmune disease. These two vitamins are two of the most vital nutrients for not only proper one-carbon metabolism and methylation, but also for nutrient absorption and hormone regulation. The first of these is a vitamin that, if measured accurately, would be found to be deficient in such a large subset of the population that the governments would consider fortification. Enter the cobalamins, commonly known as vitamin B12.

There are technically four forms of cobalamin [94]. The most commonly supplemented is called cyanocobalamin. If we break apart the word into fundamental blocks, we have a cobalamin structure, which resembles hemoglobin, and this four-membered ring has a special center group, which in this case would be cyanide. This is the synthetic version of vitamin B12. That means that it is man-made, and is the cheapest supplement option. Biochemically, cyanocobalamin is the most stable form of B12. This molecular stability is the result of having the non-reactive cyanide molecule housed in the center [95]. While the amount of cyanide found in typical B12 supplementation is not inherently dangerous, it does require additional energy, such as ATP, for the body to safely excrete the cyanide from the body. This means that there is a potential net loss of ATP, or cellular energy, when this form of the vitamin is taken internally [96]. There are three better options: adenosylcobalamin, hydroxocobalamin and methylcobalamin.

To start, we need to understand vitamin B12 metabolism and deficiency. It can take a very long time to develop a vitamin B12 deficiency. This is not something that occurs overnight as vitamin B12 is stored long term in the liver, typically, anywhere from 3 to 5 years. Specifically, approximately 2–4 mg of vitamin B12 is stored in the body, of which 50% is found in the liver [95]. Of those 2–4 mg, adenosylcobalamin represents 70% of the vitamin B12 stored in the body, which is also mostly found in the liver. Humans cannot utilize a nutrient if it is only in the storage form, held captive by the liver. Thus, the non-storage form, methylcobalamin, is the main form of vitamin B12 found in the blood. Please take notice of the specific words here, this one is methylcobalamin; therefore, it has a methyl group that can be donated, located in the center of the cobalamin ring. This is important when we consider the vital role that vitamin B12 plays as the connection between one carbon metabolism and methylation. Methionine synthase and methionine synthase reductase (MTR and MTRR) recycle homocysteine back to methionine to produce SAM. This enzyme is the connection between the one-carbon cycle and methylation. MTR and MTRR must be able to convert adenosylcobalamin into methylcobalamin, gaining the methyl group from methylenetetrahydrofolate reductase (MTHFR). Lastly, there is the hydroxyl form of cobalamin, and as the name implies, it carries a hydroxyl group in the center of the cobalamin ring. A hydroxyl group is one molecule of hydrogen and one molecule of oxygen. If you remember from basic chemistry, water is made of two molecules of hydrogen bonded to one molecule of oxygen. Water is in the most stable electrochemical form; thus, a hydroxyl group will be searching for another hydrogen to stabilize its structure. This particular biochemistry allows this form of B12 to bypass several of the transport mechanisms for vitamin B12 [97]. Hydroxocobalamin and methylcobalamin are also stored, but to a lesser extent, in the muscles, bone, kidney, heart, brain, and spleen. When analyzing whole blood, methylcobalamin comprises 60–80% of vitamin B12 found in the blood and adenosylcobalamin comprises up to 20% of total plasma cobalamin [95]. It is important to remember this when measuring serum cobalamin as it is primarily a proxy for methylation status and not a true assay for cobalamin status or cellular levels.

Now that we understand the basics of cobalamin, we need to discuss how these molecules are transported and utilized in vivo. There are two major transporters for cobalamin. The first is transcobalamin I (TCN1 or haptocorrin), and it is a binding protein secreted by the salivary glands and assists in the complexes' survival from the acidity in the stomach. Once bonded with vitamin B12, and it has successfully survived digestion from hydrochloric acid (HCL), the complex travels to the intestine. Meanwhile, gastric intrinsic factor (GIF), a vitamin B12 binding protein which requires HCL for production, is produced by the parietal cells. After the TCN1/B12 complex has arrived in the less acidic environment of the intestine, the TCN1/B12 complex can then bind to the intrinsic factor formed from GIF and be absorbed in the ileum. Once inside the enterocytes of the ileum, vitamin B12 breaks apart from TCN1 to bind to TCN2, which then carries vitamin B12 to the liver [95].

TCN1 transports up to 80% of vitamin B12 and is thought to function as a circulating storage form. The remaining 20–30% of cobalamin is transported on TCN2. When cobalamin is bound to TCN1, it may prevent bacterial use of the vitamin, which has implications on and from the microbiome. In addition to being a B12 transporter, TCN2 is a major part of the secondary granules found in neutrophils connecting B12 status to the immune system [95]. If there are polymorphisms in either of these transporters, it may cause an increase in serum vitamin B12 (often even without supplementation) with an increase in the organic acid methylmalonic acid (MMA). This means that there will be high serum levels and low tissue concentration. Sometimes, if only TCN1 is present, serum levels may also be low. The use of hydroxocobalamin can bypass this transport issue and assist with repletion [95].

So, we have learned that TCN2 is involved in the function of neutrophils, but are there other, more overt autoimmune diseases associated with defects in any of these genes? The most notorious disease is pernicious anemia, which is the result of intrinsic factor deficiency or malfunction. Alterations in GIF are also associated with an increased prevalence of familial pernicious anemia, acute lymphoblastic leukemia, and high-altitude polycythemia. GIF deficiency is also responsible for many cases of non-*H. pylori* related gastritis [98]. This non-*H. pylori*-related gastritis is compounded by the presence of even a heterozygous FUT2 non-secretor variant, as FUT2 decreases GIF secretion. This circumstance would result in cobalamin deficiency [99]. On the contrary, the FUT2 secretor status is associated with elevated levels of plasma vitamin B12. This is because the non-secretor variants do not produce H-type antigens, the antigen which is present in blood group O. There is some association with decreased plasma vitamin B12 levels on non-type O blood [99].

Next, we will briefly discuss vitamin D, its receptors (VDR) and consequences associated with defects in these receptors. There are many additional resources on the associations between vitamin D and autoimmune disease beyond those discussed in this chapter. First, we will review vitamin D nomenclature. Calcidiol (25(OH)D) is the form typically measured in serum. This is a combination of both vitamin D2 and D3 levels from endogenous and exogenous sources. Next is calcitriol, or 1–25-OH(D), the active form of vitamin D. Calcidiol is converted into calcitriol and this mechanism is tightly controlled in the absence of VDR polymorphisms.

VDRs have many regulatory roles. To start, VDRs control genes and have hormone-binding and DNA-binding domains. Specifically looking at DNA, VDRs form a complex with the retinoid-X receptor (vitamin A receptor), and that heterodimer is what binds to DNA, either turning it on or turning it off (vitamin A and vitamin D are required cofactors) [100]. In most cases, VDRs activate transcription and gene expression, but VDRs have also been known to suppress transcription. The affinity VDRs have for calcitriol, the active form of Vitamin D, is roughly 1000×x greater than its affinity for calcidiol [100]. Thus, VDRs are specifically implicated in epigenetic control. Pollutants like smoke and lack of sunshine all contribute to the function of VDR and disease [100]. VDRs also control calcium homeostasis. Certain VDRs can theoretically elevate calcitriol while lowering calcidiol. Calcitriol increases the level of calcium in serum by increasing the uptake of calcium from the intestines, increasing the release of calcium from bones [100]. VDRs are also involved in tissue modulation. They can regulate apoptosis, cellular proliferation and differentiation via matrix metalloproteinases and plasminogen activators. They also modulate the immune system and have the potential to modulate B cells, T cells, dendritic cells, monocytes, and natural killer cells. Low levels of vitamin D, calcitriol specifically, are associated with autoimmune disease [100].

Here are four VDR SNPs that may be encountered. The first represents a causal link to cancer development. It was found that rs2107301 (T;T) homozygotes were associated with an ~2.5× higher risk of prostate cancer compared to homozygote carriers of the more common (C) allele in the 630 Caucasian patients studied [101]. Vitamin D status as an epigenetic influencer can ultimately increase one's risk for prostate cancer, elucidating the importance of vitamin D repletion. Interestingly, vitamin D status is also a regulator for melanoma, suggesting that those that spend more time indoors are ultimately at an increased risk for both forms of cancer [102].

There are two other *commonly reviewed* VDR SNPs; however, the evidence for and against them is inconclusive. These two SNPs are called VDR fok and VDR taq. The first has circumstantial evidence to suggest that polymorphisms can result in blood sugar regulatory issues. VDR-taq SNPs are also circumstantially linked to better tolerance of methyl donors and may cause a decrease in calcidiol levels [103, 104]. Unfortunately, there is insufficient evidence to support nutrigenomic interventions based on these SNPs.

Lastly is VDR-bsm. This VDR provides instructions for making nuclear vitamin D receptors and is involved in the binding of calcitriol and calcitriol receptor activity. When the risk allele A is found in rs1544410, women have an increased risk of low bone mineral density. Conversely, a 26 study meta-analysis estimated a decreased risk of osteoporosis associated with the G;G genotype [103, 104]. Clinically, this VDR often causes rapid conversion of vitamin D2/3 to the active form calcitriol. This over-conversion results in elevated calcitriol/1,25-dihydroxy vitamin D with normal to low 25(OH)D levels. This phenotype erroneously presents with an apparent vitamin D deficiency, because calcidiol is low. However, the gene activating, hormone modulating, immune system influencer calcitriol is too high. In these cases, the patient is often prescribed more supplemental vitamin D, which can result in adverse reactions like nausea, dizziness, syncope, tachycardia, and autoimmunity [105]. Calcitriol initiates the transcription of genes of your immune system (modulates B cells, T cells, dendritic cells, monocytes, and natural killer cells). If there is not enough calcitriol, these genes are not activated. However, if there is too much calcitriol from VDR bsm, these immune cells receptors are blocked. As you can see, at either end of the spectrum there

is a connection between inflammation, autoimmunity and VDR bsm SNPs [106]. An interesting intersection to methylation is that excess calcitriol causes more copies of the cystathionine beta synthase (CBS) gene to be transcribed, thereby increasing hydrogen sulfide and may exacerbate transsulfuration/detoxification issues. Please see ▶ Chap. 18 for more information on CBS [107].

17.3 Epigenetics of Cancer

Cancer is a multifactorial disease state that, again, could have an entire textbook devoted to epigenetic regulation. In this section, we will bridge mitochondrial insufficiency and disease to key cancer pathway genomics. We will begin with an overview of glutathione synthesis. This begins in transsulfuration with an enzyme called CBS. This enzyme is responsible for the catabolism of a regulatory molecule homocysteine into our endogenous antioxidant, glutathione. When there is proper function of CBS, the results are taurine, sulfate and glutathione; all anti-inflammatory biomolecules, if within normal limits. In a normally functioning CBS, hydrogen sulfide enhances the production of reactive oxygen species (ROS) while simultaneously increasing glutathione, the cells' self-protection mechanism against ROS. This results in a net zero of ROS. Hydrogen sulfide in physiological dosages is beneficial to mitochondrial function as it protects it from cytotoxicity. In the case of ischemia, hydrogen sulfide actually blocks cytochrome oxidase, resulting in a decrease in mitochondrial damage. It also upregulates an important mitochondrial detoxification enzyme called superoxide dismutase (SOD) while concurrently decreasing ROS. Hydrogen sulfide is also a regulator of apoptosis, a precursor to sulfation and acts as a neuroprotectant by increasing glutathione and moving another important enzyme, cystathionine gamma lyase (CGL – also vitamin B6 dependent) to the mitochondria which results in an increase of cellular ATP [108].

However, there are variants for this CBS enzyme (Fig. 17.3) that result in up or down regulation of this process. While somewhat controversial, clinically, CBS upregulation can result in sulfur sensitivity, meaning there is an increased sensitivity to sulfur-containing foods and drugs. In upregulation (CBS C699T), we end up with excess sulfate, glutamate, ammonia, and cortisol with decreased levels of glutathione, all of which are inflammatory. This results in a net increase of ROS and the excess hydrogen sulfide interferes with proper mitochondrial function [108]. In downregulation (CBS A360A), there is a functional block that results in elevated levels of homocysteine, a higher incidence of CVD, and decreased glutathione due to limitation [109]. Glutathione is also processed through the gamma-glutamyl cycle, which is a transport system for the amino acids that form glutathione, cysteine, glutamate, and glycine. If there is a decrease in glutathione in the absence of a CBS upregulation, investigating SNPs within this cycle could provide an etiology to the deficiency [110].

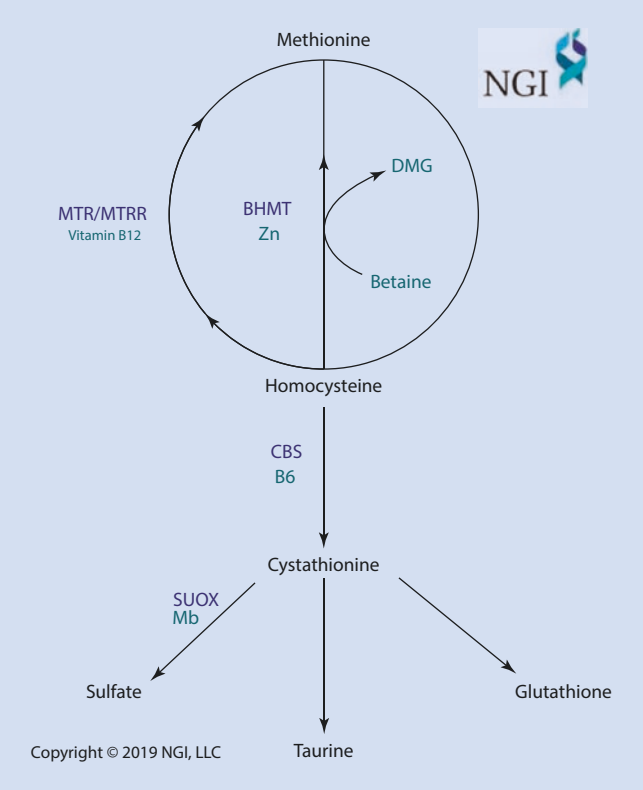

Fig. 17.3 Transsulfuration and CBS upregulation. There are three regulatory pathways of homocysteine recycling to consider: MTR/MTRR, BHMT, and CBS; CBS is the only disposal route. CBS upregulation will result in decreased levels of homocysteine, whereas CBS downregulation will result in elevated levels of homocysteine. (Courtesy of Nutritional Genomics Institute, LLC)

Now that we know how glutathione is produced and have an introduction to a few of the regulatory mechanisms, what does glutathione have to do with cancer? There are two glutathione-S-transferase genes that are directly implicated in cancer prevalence. These enzymes are responsible for binding the powerhouse antioxidant, glutathione, in its special reduced form, to toxicants, which assists in the cytochrome P450 system's removal of them. These genes, rather the absence of them, have a defined role in human carcinogenesis.

Glutathione S-transferase theta 1 deletion (GSTT1) conjugates reduced glutathione along with many exogenous and reactive oxygen species (hydrophobic electrophiles). It is absent in 38% of the general population [111]. This enzyme is concentrated in the liver, heart, brain, skin, and blood and the deletion results in a higher prevalence of cancer development in these tissues [111]. Glutathione S-Transferase Mu 1 (GSTM1) also conjugates reduced glutathione and functions in the detoxification of electrophilic compounds, including carcinogens, therapeutic drugs, environmental toxins and products of oxidative stress [112]. Null mutations or deletions in this gene are associated with an increase in various cancers and compromised detoxification [112]. Both enzymes are associated with vitamin C deficiency [113]. Not having the coding genes for either of the enzymes places one

at considerable risk for the development of several types of cancer, depending on the environmental toxin exposure. In addition to vitamin C deficiency status, both enzymes can be modulated by selenium and vitamin E [114].

In addition to these glutathione- and transsulfuration-related genes, there are also acetylation-related genomics. The N-acetyltransferase 1 and 2 (NAT1 and NAT2) proteins are involved in phase II xenobiotic metabolism and help with the biotransformation of aromatic and heterocyclic amines. It also detoxifies hydrazine and acrylamine drugs [115]. This is done via N-acetylation, which results in the detoxification of monocyclic aromatic amines. This detoxification process is ultimately responsible for the formation of DNA adducts, or a segment of DNA bound to a cancer-causing chemical that precipitates the onset of cancer development.

NAT2 is specifically responsible for the detoxification of smoke, caffeine, drugs, exhaust fumes and many other environmental toxins (heterocyclic aromatic amines). Drugs reported to be metabolized by NAT2 include isoniazid, sulfadimidine, hydralazine, dapsone, procaine amide, sulfapyridine, nitrazepam and some sulfa drugs [116]. These polymorphic conditions can result in fast and slow acetylators (N-acetyl transferase) phenotypes. The slow acetylators have a higher incidence of breast, lung, colon, head and neck, and bladder cancer, with the latter seeming to be the predominant cancer for this group [117]. The fast acetylator variants predominantly result in colon cancer [117]. The key to assisting these enzymes is to reduce the toxin exposure to reduce the stress on these enzymes. Avoidance of smoke, pesticides, insect sprays, charred meats, red meat, metal toxicity, chemicals, and solvents and the addition of acetylators like darkly colored fruits and vegetables high in anthocyanins balanced with adequate fiber will help mediate the cancer predisposition.

Next, let us look into regulatory pathways for cancer. The first is a tumor suppressor gene that regulates apoptosis, phosphatase and tensin homolog (PTEN). There are several diseases and cancers associated with a loss of PTEN function: Bannayan-Riley-Ruvalcaba syndrome, Cowden disease, Cowden syndrome-like phenotype, Cowden syndrome, endometrial carcinoma, Lhermitte-Duclos disease, macrocephaly/autism syndrome, malignant melanoma, oligodendroglioma, PTEN hamartoma tumor syndrome with granular cell tumor, prostate cancer, proteus syndrome, squamous cell carcinoma, head and neck and vertebral (V) abnormalities, anal (A) atresia, tracheoesophageal (T) fistula, esophageal (E) atresia, renal (R) abnormalities (VATER) associated with hydrocephalus [118]. There are several herbs and vitamins that can either upregulate or downregulate this enzyme. Substances that would upregulate this enzyme, or agonists, include astragalus, butyrate, honokiol, retinoic acid, and vitamin D [119, 120]. PTEN is also increased by TNF-α (pro-inflammatory cytokine), which we will discuss next. Substances that block PTEN, or antagonists, include a high fat diet and resveratrol [119, 120]. PTEN inhibition also decreases nitric oxide (NO) production, which could potentially result in hypertension and neurotransmitter imbalances.

Tumor necrosis factor alpha (TNF-α) is a pro-inflammatory cytokine that is associated with both anti- and pro-cancer effects. This means that in some cases, such as melanoma, we would not want to upregulate this enzyme [121]. However, the majority of the current research does suggest that for most cancers, it would be wise to upregulate this protein, as it is pro-inflammatory to the cancer itself. Like PTEN, there are several factors that can increase or decrease transcription. Agonists include cannabidiol, echinacea and larch arabinogalactan while antagonists include astragalus, andrographis, resveratrol, alpha lipoic acid, vitamin C, ubiquinol, curcumin, and *Lactobacillus rhamnosus* [122–127]. As evidenced, there are many common interventions that are actually epigenetic modulators that can ultimately increase or decrease one's overall risk of cancer development.

17.3.1 Epigenetics of Mitochondrial Insufficiency

Mitochondrial function was alluded to in regard to cystathionine gamma-lyase. Without a full review of mitochondrial function, we will focus on several key regulatory enzymes. As a refresher, mitochondria are the cells' powerhouse for ATP production. There are five major complexes, and the majority of these mitochondrial genes (mtDNA) are maternally inherited. Mitochondria convert energy into ATP through the process of oxidative phosphorylation via the electron transport chain, with the final conversion being carried out by an enzyme called ATP synthase. This process is dependent on hydrogen, ubiquinol, riboflavin, niacin, carnitine, thiamine, manganese, antioxidation, and succinate [128]. Any deficiency in these biomolecules can result in a functional mitochondrial deficiency.

The first enzyme we will discuss is part of complex 1. There are eight sulfur subunits in NADH ubiquinone oxidoreductase, iron-sulfur protein fraction; however, only three have actionable interventions (NADH-ubiquinone oxidoreductase 76 kDa subunits 3/7/8—NDUFS3/7/8). Children that have severe mutations in these genes have Leigh's syndrome, which is fatal in infancy. Non-ClinVar homozygous alterations in these subunits typically respond well to treatment with riboflavin, thiamin, niacin, carnitine, and higher doses of coenzyme Q10 (coQ10) [67]. Ultimately polymorphisms increase the production of free radicals (ROS) and addressing the subunit ahead in the chain (NDUF) will lessen stress on these enzymes. Broad-spectrum antioxidants are helpful in these cases, antioxidant vitamins such as C and E, and the mineral selenium help to quench the excess ROS. Minor alterations in these enzymes can result in fatigue and exercise intolerance and typically respond well to treatment with riboflavin, carnitine and higher doses of coQ10 [128–130].

SOD 2A16V is the antioxidant enzyme responsible for mitochondrial detoxification. It codes for the superoxide dismutase 2 enzyme and its role is to bind to the oxidant super-

oxide and convert it to less toxic by-products to be processed and removed. It has the cofactor of manganese and not having this functioning enzyme increases the risk of certain cancers and idiopathic cardiomyopathy. Unfortunately, intense exercise compromises this enzyme and, in terms of intense exercise, is related to a "dose-dependent" activity rate based on the number of substitutions [131]. Thus, those with alterations in this mitochondrial enzyme should take caution with high-intensity exercise and supplement with manganese to help assist with mitochondrial function.

The COX or cytochrome C oxidase genes code for the carrier protein between complex 3 and 4. This last transfer allows for all of the built-up energy in the form of hydrogen to bind with oxygen to make water. This mechanism is the cellular requirement for breathing. Like complex I insufficiency, having multiple SNPs in these genes creates free radicals. Specifically, alterations in COX6C are associated with prostate cancer and kidney disease and COX5A has associations with sideroblastic anemia and cardioencephalomyopathy. Both of these enzymes are concentrated in heart and skeletal muscle, elucidating the associated disease pathologies [132].

The last step is the conversion of this collected energy into ATP. ATP synthase is required for the final conversion of adenosine diphosphate (ADP) into the usable form of energy, ATP. There are SNPs in the ATP5C1 gene that code ATP synthase. Alterations in this gene result in a decreased output of ATP and increased ROS. Remember, ATP is our cellular currency, and a decrease in production will ultimately result in increased ROS. Alterations in ATP synthase have also been associated with accelerated aging, ALZ and an increased prevalence for cancer [133]. Overall, we want to upregulate mitochondrial function, starting with complex one and moving along through the complexes while assuring that there is adequate antioxidation. It is important to recognize that mitochondria are sequential chains. Therefore, nutrient cofactors should be added in order and not all at one time for optimal expression.

17.4 Introduction to Pharmacogenetics

Pharmacogenomics is one of the more defined areas of personalized medicine. It describes how genes may affect a person's response to a medication, combining pharmacology and genomics to tailor medical treatment on an individual basis. This field assists physicians on the selection of pharmaceuticals, length of treatment, and dosage. Studies in pharmacogenomics work to associate SNP biomarkers with pharmaceutical treatment outcomes. Challenges occur in that related pharmaceuticals such as statins have different degrees of heritability, meaning that each must be investigated separately [134]. The modern pharmaceutical industry will often develop drugs in a genetically guided manner. This has allowed for adoption of genetic testing to be used clinically prior to prescribing a medication [135].

Phase 1 detoxification is comprised of cytochrome P450, a superfamily of enzymes with many sub-divided families that are used in detoxification. All of the cytochrome enzymes are named using "CYP" for cytochrome P450 and are followed by an Arabic numeral (i.e., CYP1, CYP2, CYP3, etc.). These families are then further subdivided into subfamilies with the addition of a capital letter (i.e., CYP1A, CY1B, CYP1C, etc.). Individual members of each subfamily are then numbered in the order they were identified (i.e., CYP1A1, CYP1A2, CYP1A3, etc.). Phase 1 detoxification converts lipid-soluble molecules entering the liver into more water-soluble intermediary metabolites. These metabolites are often more toxic, not less. A range of substances including drugs, dietary components such as charcoal-broiled meats, steroid hormones, the vitamins niacin and riboflavin, as well as xenobiotics such as dioxin, exhaust and paint fumes, organophosphorus pesticides, and fragrances may induce P450 enzymes [136].

Phase 2 detoxification includes acetylation, glucuronidation, glutathione conjugation, peptide conjugation, methylation, and sulfation. Glutathione is our primary endogenous antioxidant that is essential for proper phase 2 detoxification. Glutathione is a tripeptide formed from the amino acids glutamate, cysteine, and glycine. It accounts for approximately half of our cysteine requirements. In phase 2 detoxification, glutathione is used to conjugate and excrete toxins and drugs, making them more water-soluble. Genetic SNPs in glutathione synthase (GSS) may impair glutathione production within the gamma-glutamyl cycle [137]. This enzyme aids in the production of glutathione and requires magnesium as its cofactor. When GSS levels diminish, it is associated with hemolytic anemia [138]. Further, mutations may lead to elevation of the urinary organic acid pyroglutamate [67]. Methylation connects to phase 2 detoxification via the adjoining pathway transsulfuration. Here we see the enzyme cystathionine beta-synthase (CBS) converts homocysteine to cystathionine, which ultimately leads to the production of taurine, sulfate, and glutathione (Fig. 17.2) [139].

Acetylation is associated with the biotransformation of aromatic and heterocyclic amines. The enzymes N-acetyltransferase 1 and 2 (NAT1 and NAT2) determine whether an individual is considered to be a slow, intermediate, or rapid metabolizer. It requires two slow metabolizer alleles to result in the slow metabolizer phenotype [116, 117]. This means that the rapid metabolizer allele is dominant, and the slow metabolizer allele is recessive. Sulfation includes 12 phase 2 enzymes used in the biotransformation of drugs, hormones, and xenobiotics, as well as bioactivation of carcinogens. Sulfotransferases are important for the metabolism of drugs and endogenous compounds and convert them into more hydrophilic water-soluble sulfate conjugates that then may be excreted. Sulfotransferase 2A1 (SULT2A1) catalyzes sulfation of steroids and bile acids in the liver and adrenals [43].

Glucuronidation converts fat-soluble compounds to water-soluble compounds for excretion and conjugates drugs such as salicylates, morphine, acetaminophen, and benzodi-

azepines; xenobiotics such as phenols, polycyclic aromatic hydrocarbons, nitrosamines, aflatoxin, and heterocyclic amines; and dietary and endogenous substances such as bilirubin, melatonin, bile acid, steroid hormones, and fat-soluble vitamins [67].

Currently, pharmacogenomics is only used for a handful of current diseases and conditions such as depression, mood disorders, heart disease, cancer, asthma, and HIV/AIDS. For example, the breast cancer medication herceptin or trastuzumab, only works for women who have an overproduction of the herceptin 2 (HER2) protein [135]. Mercaptopurine is a medication used for acute lymphoblastic leukemia. It can only be used for those who do not have a genetic variant in NUDT15 c.515C>T, as it may interfere with the clearance of the drug. Improper dosing can result in severe side effects and increased risk for infection. Dosage may be adjusted to an individual's genetics. In the case of children with acute lymphoblastic leukemia, it may increase the risk of 6-mercaptopurine induced myelosuppression and may also cause liver function abnormalities [15, 135]. Lastly, the antiviral drug abacavir may only be used in HIV-infected patients without polymorphism to HLA-B∗57:01, as this SNP can be associated with severe cutaneous adverse drug reactions (SCARs) which may be potentially life threatening [140].

Warfarin genetics are one of the few cases where there is more than one genetic variant related to understanding genetic risk. Both CYP2C9 and vitamin K epoxide reductase (VKORC1) variants influence metabolism, as well as risk for side effects such as hemorrhage [141]. It is important to understand that there are several variants within these classes of gene as well that help to predict the decrease in response. For example, CYP2C9∗3 carriers have an average of 40% reduction in warfarin metabolism and CYP2C9∗2 carriers have an average of 20% reduction in warfarin metabolism [142]. SNPs in CYP2D6, CYP1A2 and CYP3A4 can be particularly relevant in pharmacogenomics as these enzymes are important for the metabolism of nearly three quarters of medications [134, 143].

The quest to find ways of perfecting cholesterol levels has led to medications that target cholesteryl ester transfer protein (CETP) and proprotein convertase subtilisin/kexin type 9 (PCSK9). CETP is associated with high levels of high-density lipoprotein (HDL) and PCSK9 is associated with low levels of low-density lipoprotein (LDL). For this reason, medications have been created as inhibitors of CETP and PCSK9 in order to raise HDL and lower LDL [135]. To round out pharmacogenomics and cardiovascular disease, there is the antiplatelet drug clopidogrel. For patients who have suffered from acute coronary syndrome, stroke or percutaneous coronary intervention, clopidogrel is used as a blood thinner. CYP2C19 status relates to variability in drug metabolism as the CYP2C19∗2 (rs4244285, c.681G>A) variant causes loss of function causing a decrease in the ability to metabolize clopidogrel and other medication inducers of CYP2C19. However, it is important to not view this enzyme–drug interaction in singularity. This one variant alone does not completely predict the drugs' efficacy. Other CYP2C19 variants may have differing effects, either inducing or inhibiting, while other genes such as PON1 and ATP binding cassette subfamily B member 1 (ABCB1) also influence the metabolism of this drug [143].

17.4.1 Final Thoughts

Epigenetics and the technology associated with the "omics" revolution have and will continue to shape the way medicine and precision nutrition is practiced. As with the FTO SNP revolution, this field requires constant review of (and contribution to) the literature and an ever-expansive open mind. It is imperative that practitioners view the complex interactions between diet, lifestyle, genomics, and medications to accurately practice precision medicine and nutritional genomics. In essence, one may not "treat" a SNP or combination of SNPs. Rather, practitioners of the future will be required to not only understand genetics, but also epigenetics, genomics and the complexity of influencers that determine gene expression.

18.1 What Is Nutritional Genomics?

Nutritional genomics is comprised of both nutrigenomics and nutrigenetics. Ordovas and Mooser define nutrigenomics as the exploration of the effect of nutrients on the genome, proteome, and metabolome, whereas nutrigenetics looks at the effect of genetics on the interaction between diet and disease [1]. Nutrigenomics falls clearly in the scope of practice of nutritionists, dietitians, and other health professionals that practice nutrition, whereas genetic counselors and geneticists more appropriately practice nutrigenetics as it involves diagnostics and disease prediction. Nutrigenomics is more about understanding the unique, *measurable* nutritional needs an individual might have based on single-nucleotide polymorphisms (SNPs). Simplistically, one can think of an SNP as a genetic spelling mistake where one letter is substituted for another. They may occur in coding regions, noncoding regions, or intergenic regions. In order to be classified as an SNP, two or more versions of a sequence must each be present in at least 1% of the general population [2]. An SNP is not altogether different from a point mutation in that both include a change in a base pair (adenine, guanine, cytosine, and thymine); however, an SNP is not always deleterious in nature [3]. As alluded to, SNPs can be variable in their effects. Some can cause positive changes while others may be more detrimental. Some SNPs increase enzyme activity while others decrease enzyme function, referred to respectively as up- or downregulation [3]. This change in enzyme activity can impact nutrition as each enzyme has one or more cofactors. Thomas Devlin in the *Textbook of Biochemistry with Clinical Correlations* defines a cofactor as an "ion or molecule that on binding to the catalytic site of an apoenzyme renders it active" [4]. Typically cofactors are vitamins and minerals; therefore, SNPs that have been epigenetically activated have the potential to cause micronutrient deficiencies. This is particularly true for upregulated variants as they will quickly use up body stores of the requisite nutrient. By increasing the intake of a required nutrient it is, therefore, possible to improve enzyme function and potentially compensate for a deleterious SNP.

18.2 How Are Diseases Inherited?

An autosomal gene is located on a numbered chromosome and typically affects both males and females in the same manner. For every gene there are two alleles. One allele is inherited from the mother and the other from the father. When there is an absence of genetic change in either allele, we refer to this as the wild type. When one contains a mutation and the other does not, this is called a heterozygous mutation. When both alleles contain an alteration, this is called a homozygous mutation. In autosomal inheritance, if both parents are heterozygotes, there is a 50% chance that the offspring will be heterozygous and, therefore, affected by the condition. In many diseases, this is considered to be the "carrier" status [5]. Conversely, there is also a 25% chance that the offspring will be homozygous recessive, and, therefore, be severely affected by the disease. Similarly, there is also a 25% chance that the offspring will not have any mutations at all. The probability of inheriting such a mutation is often plotted using a Punnett square (See Table 18.1). In 1912, Cambridge University professor of genetics Reginald Crundall Punnett created a square that illustrated Mendelian inheritance [6]. This is classical inheritance. The majority of SNPs analyzed in the field of nutrigenomics consist of epigenetically activated SNPs that may or may not follow Mendelian inheritance patterns; thus caution is advised in the interpretation of nutrigenomic SNPs in this classical fashion (Table 18.1).

Table 18.1 Example of a Punnett square with one parent's gene running horizontally and the other vertically

Father's genes	Mother's genes		
		a	**a**
	A	Aa	Aa
	a	aa	aa

The genetic possibilities of the offspring are created by taking a gene from each parent. In this example, there is a 50% chance that the offspring will be heterozygotes and a 50% chance they will be homozygotes

18.3 Epigenetics and SNPs

One may ask, is it altogether possible to be able to predict disease activity from the mere presence of an abnormality? The term "epigenetics," which was coined by Waddington in 1942, was derived from the Greek word "epigenesis" which originally described the influence of genetic processes on development [7]. Epigenetics is the study of the modification of gene expression rather than the alteration of the genetic code itself, and in this way can be considered "lifestyle" genetics. It is influenced by age, environment, diet, exercise habits, and disease state. This is the biochemistry that turns "on" or "off" the "good" or "bad" genes we all have.

If you will recall the basic variations of genomic alterations, an SNP and a point mutation both confer a change to a base pair; however, the point mutation is always deleterious [3]. The SNP may be beneficial, neutral, or deleterious [8]. Thus, herein lies the question of predictability. If we can make the assumption that most SNPs confer disease risk, then we would be likely to find a linear association to demonstrate this phenomenon. However, epigenetics, or the ability to turn on and off genetic expression via lifestyle alterations, explains why an individual might have an SNP and have no effect while another individual with the same SNP may experience a change. *In essence, there may be evidence that there is a deleterious SNP, but that does not make the SNP active.* For example, 80–85% of women who carry the BRCA1 or BRCA2 genes go on to develop breast cancer [8]. How then do the

other 15–20% escape this fate? It is most often associated with their diet, lifestyle, and their parents' and grandparents' diets and lifestyles. The idea that your grandfather survived the potato famine and, therefore, he confers activated genetics to increase your risk of diabetes does seem a bit unfair [9], but not from the perspective of the genome. The alteration actually increased your grandfathers' survival during a time of stress, despite increasing your risk for diabetes in times of plenty [9].

Epigenetic influence can be measured by analyzing the metabolome, proteome, virome, microbiome, epigenome, and transcriptome [10]. Currently, in the realm of nutrition, there is a heavy focus on the microbiome and metabolome. In these analytes, we are able to pinpoint genomic expression, activation, and deactivation. The entirety of this practice is outside of the scope of this textbook; however, herein are a few examples to demonstrate the effectiveness of functional testing.

In the case of cystathionine beta synthase (CBS) upregulation, a practitioner would want to "validate" that a heterozygous or homozygous mutation was in fact epigenetically active. To do so, they would look at an organic acid marker called xanthurenate. This marker identifies functional pyroxidine (B6) deficiencies [11]. Pyroxidine (vitamin B6) in the active form is called pyridoxal-5-phosphate, and it is the cofactor for CBS. When the CBS enzyme is actively upregulated, there will be an elevation of xanthurenate which "confirms" that this cofactor is in fact being depleted. Further, in the case of CBS upregulation, one would also expect to find a decreased level of certain amino acids such as homocysteine, methionine, and potentially an increase in cystathionine [11]. CBS upregulation may also result in elevated levels of ammonia and/or glutamate, a potential outcome of excess cystathionine. Therefore, one would expect to find a supportive pattern in both organic acids and amino acids testing that points to ammonia excess. There would be potential amino acid abnormalities in glutamate, arginine, citrulline, aspartate, fumarate, and nitric oxide as well as elevations in the organic acid markers orotate, citrate, isocitrate, and cis-aconitate [11]. Why is this clinically important? It allows a practitioner to understand the importance of not formulating a nutrition plan simply by the genetics alone. Rather, it is essential to explore the confluence of the genome and the metabolome so that the nutrition plan reflects the current epigenetic expression and not simply the potential of what the genome could represent. One may have an upregulated CBS variant; however, unless the metabolomic scenario described above is present to confirm or validate the epigenetic activity of this SNP, there is no need to "treat" the SNP.

In the case of gastrointestinal dysbiosis, there is an organic acid marker called D-lactate. SNPs in fucosyltransferase 2 (FUT2) may result in an elevation of this marker [12]. A practitioner would want to "confirm" this type of genomic alteration by analyzing a stool sample, specifically looking for significantly decreased amount of *Bifidobacteria*. Decreased levels of *Bifidobacteria* inhibit bacterial competition, which results in *Lactobacillus* overgrowth [10]. In the case of elevated D-Lactate and decreased levels of *Bifidobacteria,* it would be contraindicated to recommend any probiotic strain or food item that contained *Lactobacilli* [11]. Signs and symptoms of D-lactic acidosis include altered mental status (drowsiness to coma), slurred speech, disorientation or impaired motor coordination, hostile, aggressive, abusive behavior, inability to concentrate, nystagmus, delirium, hallucinations, irritability, excessive hunger, headache, weak, droopy eyelids, hand tremor when the wrist is extended, and blurred vision [11]. As indicated, there are a wide variety of clinical signs and symptoms as well as confirmatory metabolomic and microbiome data that can indicate whether an SNP is "active" or deleterious. *Do not treat an SNP; first confirm that it is active.*

18.4 One-Carbon Metabolism Basics

One-carbon metabolism can be thought of as a folate conversion system. This system moves only one carbon at a time, creating oxidized or reduced forms of folate. This is beneficial because uncoupled carbons are highly volatile and result in oxidative stress. There are three molecules that participate in this process. The first is tetrahydrofolate (THF), the usable form of folate in the body. However, to generate THF, first dihydrofolate (DHF) or dietary folate must be converted into tetrahydrofolate (THF) by dihydrofolate reductase (DHFR) [13]. DHFR not only preferentially metabolizes dihydrofolate, but it is also subject to negative feedback inhibition via synthetic folic acid, and thus can be functionally blocked by excessive folic acid consumption [14]. If there is a polymorphism in DHFR, it is prudent to supplement with forms of folate that bypass this system, such as folinic acid. Folinic acid is available in a supplemental form as calcium folinate and as the prescription drug Leuvocorin [15]. The goal is to get to the least oxidized state; for one-carbon metabolism that is 5-methyltetrahydrofolate, the product of MTHFR. As a reminder, methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10-methylenetetrahydrofolate (an intermediate level of oxidation) to 5-methyltetrahydrofolate (the lowest level of oxidation), a co-substrate for homocysteine remethylation to methionine [16]. The highest oxidative state for folates is the formino or formyl form. These metabolites are formed when there is an increase in cellular oxidation as a result of cellular folate deficiency, potentially caused from alterations in MTHFR and/or DHFR.

The next player on this carbon team is called S-adenosylmethionine or SAM. SAM is considered to be the universal methyl donor [17] as it is formed from methionine and then "donates" or releases the carried methyl donor for processes such as purine and neurotransmitter synthesis. Once SAM has released its methyl donor, it is converted into S-adenosylhomocysteine (SAH), the intermediary between SAM and homocysteine. At this point, homocysteine is either converted back to methionine via methionine synthase (MTR) or betaine homocysteine methyltransferase (BHMT) or it can enter the transsulfuration pathway to form other sulfur-

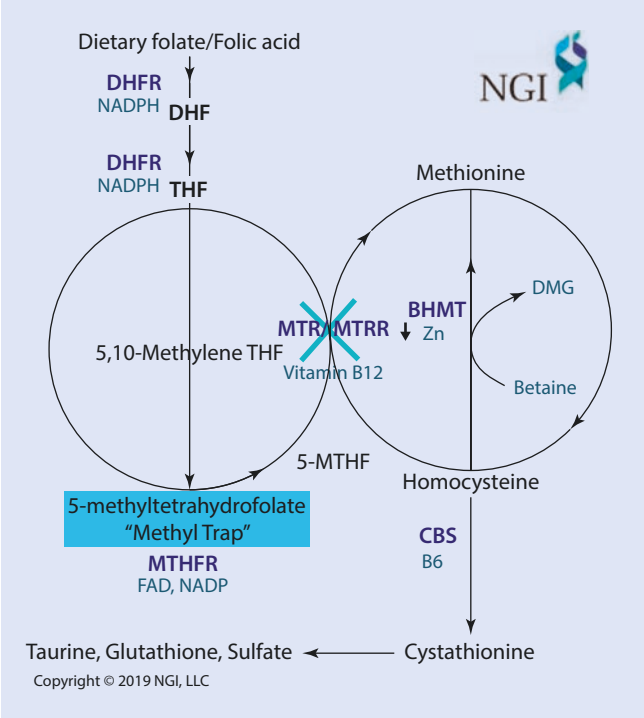

Fig. 18.1 Methylation cycle: homocysteine sits at the bottom of the methylation pathway. It may be remethylated to methionine via MTR/MTRR or via BHMT. Alternatively, it may be converted to cystathionine via CBS and is the only true disposal route (transsulfuration)

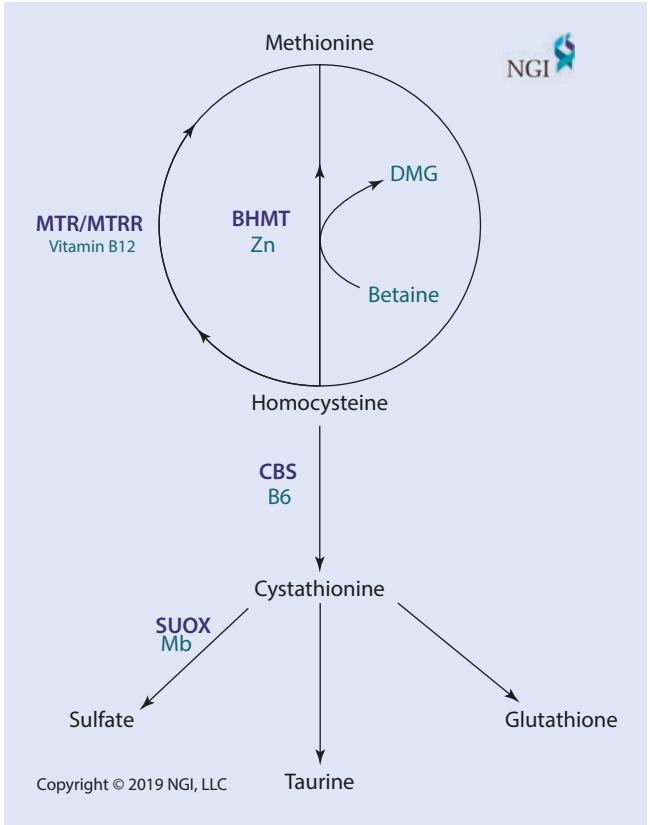

Fig. 18.2 The pathway on the left is one-carbon metabolism. This pathway's ultimate goal is to use folate for formation of a methyl group via the creation of 5-methyltetrahydrofolate. This methyl group is then passed off to the pathway on the right, methylation. Here, the methyl group is accepted by vitamin B12, transforming it from the adenosylcobalamin form to the methylcobalamin form. Methylation then recycles this methyl donor to aid in DNA regulation (epigenetics). When there is insufficient vitamin B12 available to accept the methyl donor from folate, it becomes trapped in the 5-methyltetrahydrofolate form and is unable to be converted back to THF, the usable form of folate in the body. This is what is referred to as the folate trap. In summation, one-carbon metabolism is a methyl donor creation center, and methylation is a methyl donor recycling center with MTR/MTRR being the connection between the two pathways

containing amino acids such as cysteine and taurine [18]. This process of SAM moving methyl donors around to homocysteine is again called methylation (Fig. 18.1). This is an oversimplification of this process as there are many additional fates of SAM; however, this is the basic process of recycling the methyl donor that has been created in one-carbon metabolism by MTHFR.

The last player is cobalamin or vitamin B12. MTR takes the methyl donor created by MTHFR (5-methyltetrahydrofolate) and converts the storage form of vitamin B12 known as adenosylcobalamin into a usable methyl recycler known as methylcobalamin. It is actually methylcobalamin that transfers the methyl donor from MTHFR to form methionine which in turn forms SAM. Methionine synthase and the methylcobalamin it forms are also partially responsible for homocysteine catabolism (Fig. 18.2).

Within this system of one-carbon metabolism, there is a phenomenon referred to as "folate trapping." Referring back to the reaction of MTHFR, the conversion from 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate is irreversible. This means that when 5-methyltetrahydrofolate tries to convert back into tetrahydrofolate it must be able to hand off the methyl group to successfully convert adenosylcobalamin into methylcobalamin. It must also convert back into the folate cycle substrate THF. If, for some reason, this conversion cannot occur, there could potentially be either a polymorphism in MTR or a vitamin B12 deficiency. In this circumstance, MTR cannot recycle vitamin B12 into the methylation cycle and the folate will get "trapped" in the methylated form. Please note the nomenclature; the only difference between *methyl*-tetrahydrofolate and tetrahydrofolate is the addition or subtraction of a *methyl* group [19]. Clinically this will result in an elevation of formiminoglutamate (FIGLU) (remember, the formino form is at the highest oxidative state), indicating a cellular folate deficiency along with oxidative stress [11]. Paradoxically, it will also increase serum folate levels. This occurs because serum folate measures all forms of folate, mostly methylfolate, and FIGLU is specifically measuring usable THF [11]. If you were to erroneously add in more folate, especially methylated folate, this will increase the amount of 5-methyltetrahydrofolate, thus exacerbating the discrepancy between cellular and serum folate levels. Other clinical associations include reduced methylation capacity as evidenced by a decrease in methionine, SAM, SAH, homocysteine, and ultimately, glutathione [11]. The correct intervention is not to add in more folate as

indicated by the elevation in the urinary organic acid formiminoglutamate (FIGLU), rather it is to assist with the methyl transfer by correcting the cobalamin deficiency [11]. A cellular deficiency in cobalamin can be determined by an elevation in methylmalonic acid (MMA) [11]. In cases where there is a known polymorphism in DHFR, the importance of removing excess synthetic folate in the form of synthetic folic acid is incredibly important as a block in this enzyme will further restrict one-carbon metabolism, methylation, transsulfuration, and neurotransmitter synthesis [20].

18.5 Introduction to Methylation

Methylation is a biochemical pathway in the body that describes the adding or subtracting of a methyl group from different compounds. A methyl group is simply one carbon and three hydrogens (CH_3). At the center of methylation is homocysteine, an amino acid. The pathway works by either recycling homocysteine back to its precursor methionine or by disposing with homocysteine all together. When looking at the difference between homocysteine and its precursor methionine, it is important to understand that the only difference is the presence of an additional methyl group on methionine. In fact, methionine is methylated homocysteine. Methylation interacts with several additional pathways including transsulfuration, one-carbon metabolism, the tetrahydrobiopterin (BH4) cycle, and the urea cycle.

Methionine = homocysteine + methyl group (CH_3)
Methionine is synthesized from homocysteine and a methyl group (CH_3). This may occur by recycling homocysteine back to methionine via MTR/MTRR or via BHMT.

The National Institute of Health (NIH) defines methylation as "The attachment of methyl groups to DNA at cytosine bases; correlated with reduced transcription of the gene and thought to be the principal mechanism in X-chromosome inactivation and imprinting" [21]. Methylation is involved in gene regulation, biotransformation, neurotransmitter synthesis, estrogen catabolism, immune cell production (such as T cells and natural killer cells), DNA and histone synthesis, energy production, creation of the myelin sheath on nerve cells, and building and maintaining cell membranes via phosphatidylcholine. Nutritionally, methylation may be influenced by the presence or absence of sufficient nutrients that are required as either cofactors or substrates in the pathway. The genetics of the individual and presence of activated SNPs dictate the likelihood of requiring more or less of a particular nutrient. Pharmaceuticals such as antacids, methotrexate, and metformin may also influence methylation by decreasing the absorption of nutrients required as cofactors for the enzymes [22]. Use of high-dose niacin can also impede methylation as it absorbs S-adenosylmethionine (SAM), our universal methyl donor [23]. Exposure to environmental toxins such as heavy metals and chemicals may also inhibit methylation as these xenobiotics can block regulatory enzymes in the pathway as well as require additional glutathione production from an adjacent pathway (transsulfuration).

Stress can also have a negative impact on methylation. This relationship exists because stress influences the release of the neurotransmitters norepinephrine and epinephrine via cortisol [24]. Epinephrine, commonly known as adrenaline, is created from norepinephrine via an enzyme called phenylethanolamine N-methyltransferase (PNMT) [25]. This enzyme requires a methyl group and, when upregulated, can deplete overall methyl stores. Thus, an excessive need for conversion (stress) will place continuous demands on SAM and can negatively impact the other processes of methylation. Finally, having too much of a substrate (as in oversupplementation with methylated supplements) can cause negative feedback inhibition, which may also impede the methylation pathway by targeting certain SNPs and blocking their actions.

Remember, the presence of a genetic SNP alone is not sufficient to cause a decrease in enzyme function. An epigenetic influence must occur for this to happen.

18.6 Homocysteine Metabolism

Homocysteine is localized at the bottom of the methylation pathway as the segue to the transsulfuration pathway. It is produced from the amino acid methionine as it is methylated methionine. Homocysteine in excess or deficiency can have deleterious consequences. To address the most common issue with homocysteine (elevation), there are three routes of homocysteine metabolism. The two recycling routes are comprised of methionine synthase (MTR)/methionine synthase reductase (MTRR) and betaine homocysteine methyltransferase (BHMT). The only true disposal route is via cystathionine beta synthase (CBS) and provides a connection between the methylation and transsulfuration pathways.

MTR and MTRR recycle homocysteine back to methionine with the assistance of a methyl group produced by methylenetetrahydrofolate reductase (MTHFR). This accounts for approximately half of homocysteine catabolism. MTR is vitamin B12 dependent and assists in maintaining adequate intracellular methionine required for production of S-adenosyl methionine (SAM), the universal methyl donor [11]. It is also responsible for maintaining sufficient intracellular folate pools as it supplies a methyl donor to one-carbon metabolism [11]. In the folate cycle, MTHFR converts 5,10 methylenetetrahydrofolate into 5-methyl folate, a co-substrate of homocysteine metabolism. Then, 5-methyl folate "hands off" its methyl donor to adenosylcobalamin, in effect pushing out the adenosyl group and replacing it with a methyl group to form methylcobalamin, the usable form of cobalamin required for methylation.

MTRR assists MTR in the maintenance of sufficient vitamin B12 to support appropriate homocysteine remethylation. If it cannot perform in this role, either via an SNP or functional B12 deficiency, the 5-methyl folate becomes "trapped" and is no longer able to participate in one carbon metabolism or methylation. There is a specific methionine synthase SNP that increases homocysteine levels and may also contribute to dyslipidemia in men, known as MTRR A66G [26]. This presentation is particularly true if there is a concurrent MTHFR C677T polymorphism as the result of this SNP also increases homocysteine.

BHMT provides a short cut through methylation. It supplies a methyl group that allows for the conversion of homocysteine back to methionine as well as converting betaine to dimethylglycine (DMG). While hypothetically BHMT polymorphisms could have an effect on homocysteine levels, there is conflicting evidence to support the idea that SNPs have any measurable effects. BHMT is thought to account for up to half of the homocysteine remethylation capacity, according to some studies [27], while it is thought to account for less than 1% of homocysteine recycling in others [28]. BHMT aids MTR in increasing the availability of methionine so that it may be used to produce SAM [29]. Zinc serves as a cofactor for BHMT and a polymorphism may increase an individual's zinc requirements. Betaine is also required for the production of DMG, thus it is a necessity for proper BHMT function. Betaine may be found in foods such as wheat, spinach, shellfish, and beets and may also be created from choline endogenously [28, 30]. This pathway also intersects with choline metabolism and more advanced methyltransferases, which ultimately regulate epigenetic expression (Fig. 18.1).

CBS provides the only true disposal route for homocysteine and accounts for approximately half of all homocysteine catabolism. It catalyzes the conversion of homocysteine to cystathionine utilizing vitamin B6 and magnesium as its cofactors. This enzyme is important as it sits between the junction of methylation and transsulfuration, the pathway that ultimately leads to the generation of the endogenous antioxidant glutathione. In this way, it has the ability to influence detoxification via channeling sulfur down into the transsulfuration pathway and, ultimately, into the gamma glutamyl pathway, a mechanism for glutathione production. CBS generates both cystathionine and hydrogen sulfide (H2S) as its products. For CBS, there are both upregulated and downregulated variants. CBS C699T is considered to be upregulated and CBS A360A is downregulated [31] (Fig. 18.3).

Upregulation of CBS will cause decreased levels of vitamin B6, magnesium, glutathione, and homocysteine [11]. Vitamin B6 deficiency should be confirmed via xanthurenate before supplementing in this sensitive population [11]. Upregulated CBS can compromise the ability to recycle

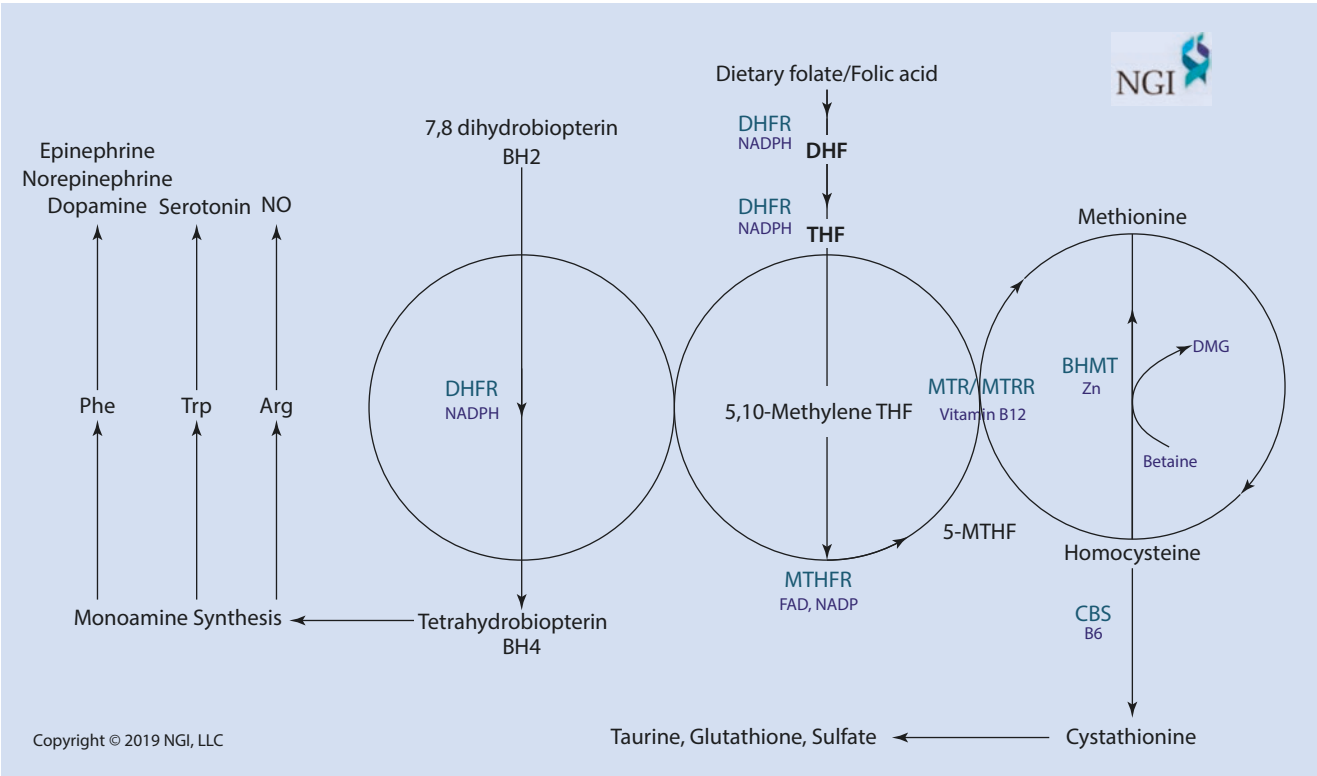

Fig. 18.3 The intersection of major biochemical pathways including one-carbon metabolism, methylation, and transsulfuration are essential for the regulation of DNA expression. They also interact with additional pathways including the gamma glutamyl cycle, which produces glutathione to be used in glutathione conjugation (phase 2 detoxification), and the tetrahydrobiopterin pathway via DHFR, which is essential as a cofactor in the production of the monoamine neurotransmitters including dopamine, norepinephrine, epinephrine, serotonin, and nitric oxide

homocysteine back to methionine and to generate SAM. Further, there will be increased generation of hydrogen sulfide, which can increase the production of ammonia, cortisol, and glutamate resulting in excitotoxicity [32]. Further, ammonia depletes tetrahydrobiopterin (BH4) through increased production of nitric oxide [30]. In this way, polymorphisms can lead to insufficient production of serotonin, dopamine, norepinephrine, and epinephrine. The CBS C699T variant is often found in those with autism, Down syndrome, connective tissue disease, cancer, and homocystinuria [33]. A high organosulfur diet in this population will cause increased urinary sulfate levels but will typically not allow for the generation of glutathione. For this reason, it may be helpful to limit high organosulfur foods such as eggs, onion, garlic, and cruciferous vegetables to tolerable quantities for a short time to relieve stress on this enzyme.

The increased flux of sulfur through CBS forces sulfur too quickly downstream which taxes sulfate oxidase (SUOX), a lower capacity enzyme. This may cause increased requirements for the mineral molybdenum, SUOX's cofactor [34]. SUOX catalyzes the oxidation of sulfite to sulfate in the final reaction in the oxidative degradation of the sulfur amino acids cysteine and methionine [34]. SNPs in SUOX are rare and, when present, can result in neurological abnormalities that are often fatal at an early age.

CBS downregulation, on the other hand, limits the sulfur amino acids by slowing the conversion of homocysteine to cystathionine. The resultant elevation of homocysteine is, therefore, associated with hypertension and other cardiovascular disorders. Similar to upregulation, this will create an increased requirement for vitamin B6 (CBS's cofactor). Like those with upregulated variants, individuals who have CBS downregulation have limited availability to generate glutathione from sulfur amino acids such as cysteine [11]. To stimulate this enzyme to form glutathione, sulfate, and taurine, supplement with P5P and, potentially, cysteine in the form of N-acetyl cysteine.

Once cystathionine is generated through CBS, it then is converted to cysteine via cystathionine gamma-lyase (CGL) [11]. This enzyme also requires vitamin B6 as its cofactor and is known to cause significantly higher plasma homocysteine levels and cystathioninuria [13]. Further, polymorphisms are associated with hypertension as this enzyme regulates blood pressure via endogenous signaling of H2S [32]. Replenishing vitamin B6 as the active pyridoxal-5-phosphate (P5P) may help restore proper enzyme function and allow for proper sulfur influx into the gamma glutamyl cycle.

18.7 Connecting Neurotransmitters to Methylation

18.7.1 Tetrahydrobiopterin (BH4)

While DHFR is a key enzyme in one-carbon metabolism, it also is an important precursor to the tetrahydrobiopterin (BH4) cycle, one that determines cellular levels of several neurotransmitters. BH4 is a cofactor required for the hydroxylation of the aromatic amino acids (i.e., phenylalanine to tyrosine, tyrosine to DOPA, and tryptophan to serotonin). BH4 is also a necessary cofactor for the conversion of arginine into nitric oxide via nitric oxide synthase (NOS) [35]. In this way, BH4 serves an integral role in the production of all of the monoamines including dopamine, norepinephrine, epinephrine, and serotonin as well as nitric oxide. Lord and Bralley state, "Restricted BH4 cofactor availability has been suggested as an etiologic factor in neurological diseases, including DOPA-responsive dystonia, Alzheimer's disease, Parkinson's disease, autism and depression; as well as in other conditions such as insulin sensitivity and vascular disease" [11].

18.7.2 Catecholamines

The synthesis of all catecholamines starts with the essential amino acid phenylalanine, which is then converted to the amino acid tyrosine via phenylalanine hydroxylase (PAH). This reaction requires both BH4 and iron as cofactors. Tyrosine is then consequently converted to L-DOPA via tyrosine hydroxylase and is the rate-limited step also using the cofactors BH4 and iron [36]. Dopamine is then generated from L-DOPA via aromatic L-amino acid decarboxylase (AADC), a vitamin B6-dependent enzyme [37]. At this juncture, there are two paths for dopamine. It may be catabolized via monoamine oxidase B (MAO-B) using flavin adenine dinucleotide (FAD) as its cofactor along with catechol-O-methyltransferase (COMT) using magnesium and SAM as its cofactors to form the urinary organic acid homovanillate (HVA) [11, 36]. Alternatively, dopamine may also be used to generate norepinephrine via dopamine beta hydroxylase (DβH) [22]. This reaction requires copper and ascorbate as its cofactors. Norepinephrine may then be catabolized by COMT and MAO-B to the urinary organic acid vanilmandelate (VMA), or it may be converted via COMT to epinephrine, which ultimately is also catabolized by COMT and MAO-B to VMA [11, 22].

COMT is highly polymorphic and is a very common clinical finding. More often, heterozygosity is found rather than homozygosity. This enzyme is important not only for the transfer of methyl groups from SAM to the catecholamines but also from SAM to catechols from foods (e.g., green tea and potatoes), catechol antioxidants such as quercetin, and the hormone catechol estrogen [38]. Additionally, this enzyme is essential for the catabolism of dopamine, norepinephrine, and epinephrine [38]. Research has shown that the COMT Val allele is related to the presence of higher anxiety. This is likely due to the effect of COMT on the dopaminergic tone in the prefrontal cortex and the resultant effect on cognition [39]. There is some thought that gender may also be a factor in anxiety secondary to the COMT val158met polymorphism due to this enzyme's necessity in the catabolism of estrogen. Therefore, women are more likely to experience higher levels of anxiety than men [39].

Since methyl donors help to upregulate the production of monoamines, including the catecholamines, they may be problematic for those with epigenetically activated (downregulated) COMT SNPs. While methyl donors should not necessarily be avoided in the long run, it is important to insure proper COMT function prior to supplementation. When supplementing vitamin forms that contain methyl donors such as methylcobalamin, L-methylfolate, and trimethylglycine, many practitioners consider it important to dose only small amounts in the presence of COMT since hypothetically methyl donors may increase production of catecholamines, which could tax COMT. These supplements may be dosed several times per week rather than daily as another way of preventing increased anxiety.

Given that magnesium is the cofactor for COMT, the presence of a polymorphism supports investigating erythrocyte (RBC) magnesium levels and supplementing with a well-absorbed form of magnesium if needed. Some forms of magnesium, such as magnesium sulfate, oxide, and citrate work as osmotic laxatives and are not very well absorbed [40]. Magnesium glycinate is well absorbed and may provide an additional calming effect since it is chelated to the amino acid glycine, which also serves as an inhibitory neurotransmitter [41]. Another good option is magnesium threonate as it is the only form of magnesium that may cross the blood–brain barrier [42].

MAO-B catalyzes the oxidative deamination of biogenic and xenobiotic amines (i.e., histamine and tyramine), is a part of the metabolism of neuroactive and vasoactive amines in the central nervous system and peripheral tissues, and preferentially oxidizes dopamine (as opposed to MAO-A, which preferentially oxidizes serotonin and noradrenaline). Variants include rs1799836, rs10521432 (C112982T), and rs6651806 (T57758G). MAO-B inhibitors are a type of pharmaceutical that is often used for those with Parkinson's disease to slow the breakdown of dopamine.

18.7.3 Serotonin

In serotonin synthesis, the pathway begins with the amino acid tryptophan being converted to 5-hydroxy-tryptophan (5-OH-TRP) by tryptophan hydroxylase (TPH) using both BH4 and iron as its cofactors [11]. 5-OH-TRP is consequently converted to serotonin by AADC [11]. Monoamine oxidase A (MAO-A) is then used to break serotonin down into the urinary organic acid 5-hydroxyindoleacetic acid (5-HIAA) [11].

MAO-A SNP rs6323 is an upregulated variant causing increased enzyme activity leading to decreased amounts of amines. The G variant encodes for higher activity. A study by Slopien et al. in 2012 found that there was a particularly high rate of depression in postmenopausal women that had this variant and that there was MAO-A activity ranging more than 50-fold over controls [43]. This enzyme also has downregulated variants including rs5906883, rs5906957, rs909525, rs9593210, and rs2072743. These downregulated variants decrease enzyme activity leading to increased amounts of amines such as serotonin (Fig. 18.4).

Serotonin is considered to be the neurotransmitter most closely associated to depression. A common nutritional intervention for depression is to supplement folate. This intervention is effective because folate (5-MTHF) is responsible for regenerating oxidized BH4. When there is insufficient BH4, 5-MTHF may be substituted for BH4 at the enzymatic level. This is due to the similarity in chemical structures of BH4 and 5-MTHF, enough so that endothelial nitric oxide synthase (eNOS) can use 5-MTHF as a substitute cofactor [12]. This may account for folate's antidepressant effect.

18.7.4 Iron and Neurotransmitters

Iron is a cofactor, along with BH4, for PAH, TH, and TPH. This may account for why patients with iron-based anemia often struggle with mood. Without sufficient iron, the enzyme tryp-

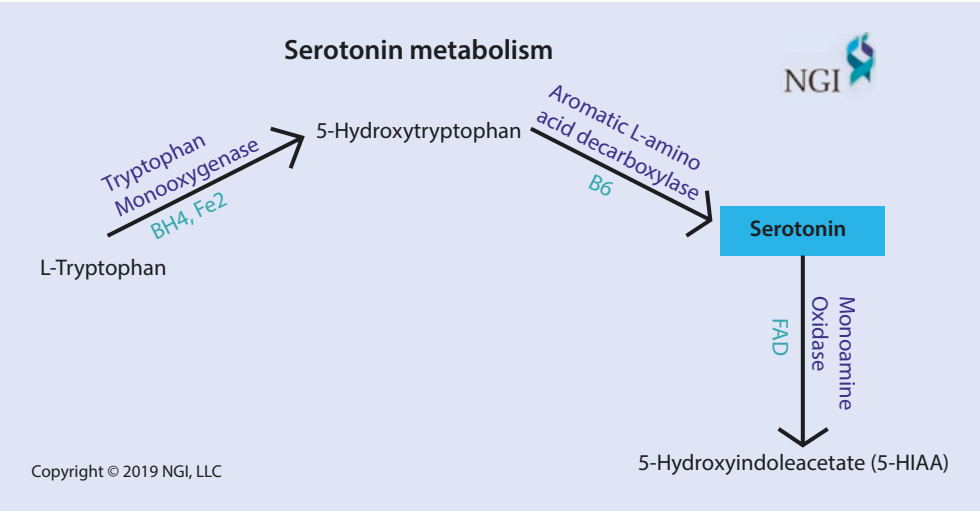

Fig. 18.4 Tryptophan is the precursor of serotonin and is metabolized by tryptophan monooxygenase with the cofactors of BH4 and iron to 5-HTP followed by AADC with the cofactor of P5P. Monoamine oxidase A preferentially catabolizes serotonin and uses the cofactor FAD to create the organic acid metabolite 5-HIAA

tophan dehydrogenase is unable to convert the amino acid tryptophan into the intermediate 5-hydroxy-tryptophan, which is ultimately converted to serotonin by aromatic L-amino acid decarboxylase (AADC) using its cofactor vitamin B6 [37]. This will cause a decreased capacity to synthesize serotonin which, when deficient, is the major neurotransmitter associated with depression. Some depression, however, may also be dopamine mediated. Iron deficiency anemia can also impact this type of depression as dopamine synthesis relies on the conversion of phenylalanine to tyrosine via the enzyme phenylalanine hydroxylase (PAH). This enzyme relies on both BH4 and iron as its cofactors [37]. Additionally, the conversion of tyrosine to L-DOPA is also iron and BH4 reliant as tyrosine hydroxylase requires these nutrients as cofactors. It is then L-DOPA that may be converted into dopamine via the enzyme AADC in both the central and peripheral nervous systems [22] (◘ Figs. 18.5 and 18.6).

Nitric oxide (NO) is synthesized from the amino acid arginine and is produced in the endothelial cells of blood vessels. It is a gaseous substance that diffuses readily through membranes and helps to regulate blood flow by dilation of muscles encircling blood vessels. Therefore, nutritionally, a relative arginine deficiency can occur in diseased coronary arteries. As such, replenishing arginine may allow for arterial dilation. NO can also help control glucose uptake by muscles [44]. This neurotransmitter is unstable and acts quickly, undergoing oxidation to nitrite or nitrate within seconds [44]. It plays an important role in neurotransmissions, blood clotting, and control of blood pressure (via endothelium-derived relaxing factor activity) [44]. Nitric oxide synthase (NOS's) ability to influence smooth muscle reaches beyond the cardiovascular system and allows for regulation of other smooth muscle actions such as peristalsis [44]. Further, NOS is associated with the neurotoxicity found in stroke and other

neurodegenerative diseases [45]. In the immune system, it helps to stimulate immune cell activation and helps neurons regulate their function [4].

Low levels of NOS can impact male fertility by causing erectile dysfunction (ED) [46]. This is because NO is the primary biochemical way that an erection is stimulated via the corpus cavernosum [47]. Phosphodiesterase 5 (PDE5) inhibitor medications such as Viagra® capitalize on this mechanism, though they were not originally designed for this purpose. In fact, it was not until Viagra® was used in a phase I clinical trial for the treatment of angina that the medication's "side effect" of penile erection was discovered [15]. Viagra® allows for blood vessels within the erectile tissue to vasodilate in response to released NO as well as for the activation of guanylate cyclase (cGMP). Viagra® inhibits breakdown of cGMP causing increased and sustained levels of cGMP, thus causing vasodilation in erectile tissue [4].

There are three different forms of nitric oxide synthase (NOS 1–3). All three enzymes catalyze the conversion of arginine to nitric oxide using NADPH and NADP+ as cofactors [44]. This reaction also creates the byproduct citrulline [11]. It is possible to test NOS activity via urinary organic acid testing, specifically looking for increased levels of citrulline. NOS1 encodes neuronal nitric oxide synthase (nNOS) and is found in nervous tissue and skeletal muscle where it is involved in cell communication [48]. Key variants include rs7298903 (A57373G), rs3782206 (G59494A), and rs2293054 (T2202C). NOS2, or inducible nitric oxide synthase (iNOS), is considered a reactive free radical involved in neurotransmission along with antimicrobial and antitumor activities [48]. In this way, it may be induced by lipopolysaccharides and cytokines, allowing it to serve as an immune activator to help defend against pathogens. Found in both the immune and cardiovascular systems, elevations are commonly found in inflammatory disorders [49].

Via iNOS, NO may play a role in cancer, though this mechanism is not well understood. It may have the potential to stimulate tumor growth, development, and progression as well as angiogenesis [49]. Due to the precursory nature of arginine to NO, a low arginine diet has been suggested as a means of controlling cancer progression [50]. Key variants include rs2297518 (C1823T), rs2248814 (T32235C), and rs2274894 (T836165G). Endothelial nitric oxide synthase (eNOS) is encoded by NOS3 [51]. Found in the endothelium, it is involved in vasodilation, vascular smooth muscle relaxation via cGMP-mediated signal transduction, mediates vascular endothelial growth factor induced angiogenesis in coronary vessels, and promotes blood clotting via platelet activation [51]. Inside the muscle cell, NOS3 binds to guanylate cyclase, resulting in activation and, consequently, catalyzing the conversion of GTP to cyclic GMP. This process ultimately leads to the activation of cGMP-activated protein kinase and the subsequent attachment of a phosphate group to the inositol trisphosphate receptor (IP3), which then results in a decrease in calcium in the muscle cells' cytoplasm [52]. This is the mechanism by which NO results in arterial relaxation. Key variants include rs1800783 (A6251T), rs3918188 (C19635T), rs7830 (G10T), rs1800779 (G6797A), and rs2070744 (T786C) (Fig. 18.7).

Interestingly, manganese appears to be another nutrient that can be used to regulate NO production [53]. This is related to arginine's ability to be converted into either ornithine or citrulline to produce urea and nitric oxide, respectively [11]. If you inhibit production of ornithine via the enzyme arginase (converts arginine and water to ornithine and urea), it will increase nitric oxide production and decrease urea production. Since manganese is the cofactor for arginase, decreasing manganese intake may allow for increased nitric oxide production that could allow for vasorelaxation. This could have positive implications for childhood asthma [11].

18.8 Final Thoughts

Methylation has far-reaching implications and plays a central role in metabolism. Methylation contributes to epigenetic activation via turning "on" and "off" genes, synthesizes neurotransmitters, and is required for the production of glutathione required for detoxification. Understanding the nutritional implications of genetic SNPs while validating these alterations by correlating it to laboratory evaluations allows medical and nutrition professionals to directly influence methylation-related biological processes that may, in turn, improve the health of the patient. This may then help prevent and treat a host of chronic disease states as we are learning that all diseases are a confluence of nature and nurture or what we now call epigenetics Table 18.2.

Table 18.2 Single-nucleotide polymorphisms (SNPs), cofactors, and functional markers

SNPs	Cofactors	Organic acids	Amino acids/other tests/interventions	rs Numbers
Methylation, transsulfuration, and one-carbon metabolism				► www.snppros.com
DHFR *Dihydrofolate reductase* Codes the enzyme dihydrofolate reductase used in conversion of dihydrofolate and folic acid into tetrahydrofolate	NADPH, BH4 re-coupling (BH4 requires magnesium)	↑FIGLU; ↓HVA, ↓VMA	Restricted neurotransmitters, ↓tyrosine, ↓trypto-phan; restricted one-carbon metabolism, ↓methionine	rs1643649, rs1643659, rs1677693, rs1650697
MTHFR C677T *Methylene tetrahydrofolate reductase* Catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, a co-substrate for homocysteine remethylation to methionine; folate trapping may increase homocysteine levels and deplete cellular folate concentrations	Riboflavin, NADH, and ATP	↑FIGLU, ↑glutaric acid	↑Homocysteine; correct B12 status to avoid folate trapping	rs1801133
MTR/MTRR *Methionine synthase/ methionine synthase reductase* Responsible for B12 recycling and converting adenosyl-cobalamin into methyl-cobalamin as needed for methylation	B12, SAM, zinc, heme MTR cofactor: Zinc, blocked by lead, aluminum, and mercury MTRR cofactors: SAM,	↑MMA	↓Methionine, ↑↓homocysteine – Check other homocysteine catabolism SNPs like CBS and BHMT	rs1801394, rs1802059, rs162036

(continued)

Table 18.2 (continued)

SNPs	Cofactors	Organic acids	Amino acids/other tests/interventions	rs Numbers
	FAD, NAD, zinc, blocked by lead			
AHCY *Adenosylhomocysteinase* Regulates intracellular S-adenosylhomocysteine (SAH) concentration and assists with methionine catabolism	NAD, SAM	SAH regulator; SAH blocks COMT and is considered inflammatory	↑Methionine, ↑homocysteine	rs121918607
SHMT *Serine hydroxymethyl-transferase* Catalyzes the reversible, simultaneous conversions of L-serine to glycine and tetrahydrofolate to 5,10-methylenetetrahydrofolate (requires SAM); also catalyzes conversion of 5,10-methenyltetrahydrofolate to 10-formyltetrahydrofolate	P5P, SAM	↑FIGLU	Potential abnormalities in glycine and serine	rs9909104 rs1979277
CBS C699T *Cystathionine beta synthase* Converts homocysteine to cystathionine; sulfur sensitivity	P5P, magnesium, blocked by lead	↑Xanthurenate	↑Cystathionine, ↑cysteine, ↑cystine, ↓homocysteine, ↑glutamate, ↑ammonia (depletes BH4)	rs234706
CBS A360A *Cystathionine beta synthase* Converts homocysteine to cystathionine; cardiovascular complications	P5P, magnesium, blocked by lead	↑↓Xanthurenate	↑Homocysteine, ↓cystathionine, ↓cysteine, ↓cystine, ↑NO	rs1801181
CGL (CTH gene) *Cystathionine gamma lyase* Associated with cystathioninuria; converts cystathionine to cystine; limiting enzyme for glutathione synthesis	P5P, NADH	↓↑Xanthurenate, alpha-ketobutyrate, alpha-hydroxybutyrate	↑Homocysteine, ↑cystathionine, ↓cysteine, ↓cystine, ↑ammonia (depletes BH4)	Primary: rs1021737
PEMT *Phosphatidyl-ethanolamine N-methyltransferase* Required in choline synthesis, hepatocyte membrane structure, bile secretion, estrogen degradation and VLDL secretion	SAM, choline, folate	↓SAM: SAH; potential ↑ in hydroxyproline (membrane fluidity)	↓Phosphoethanolamine, potentially ↓ phosphatidyl-serine and ↓phosphatidylcholine; pathway requires magnesium	rs12325817, rs7946, rs46464006, rs4244593
BHMT *Betaine homocysteine methyltransferase* Supplies a methyl group to convert homocysteine back to methionine and betaine to dimethylglycine (DMG)	Zinc, TMG; blocked by glucocorticoids	N/A Consider RBC zinc	↓Methionine, ↑homocysteine	rs3733890
SUOX *Sulfite oxidase* Is a mitochondrial enzyme; catalyzes the oxidation of sulfite to sulfate, the final reaction in the oxidative degradation of the sulfur amino acids cysteine and methionine	Molybdenum, hydroxocobalamin, vitamin E	↑sulfate, ↑pyroglutamate, potentially ↑alpha hydroxybutyrate	↓Homocysteine, ↓cystathionine, ↓cysteine, ↑taurine	rs705703

Table 18.2 (continued)

SNPs	Cofactors	Organic acids	Amino acids/other tests/interventions	rs Numbers
Neurotransmitters				
NOS1 *Nitric oxide synthase 1* Catalyzes the conversion of arginine to nitric oxideAlso creates the byproduct citrulline	NADPH and NADP+	↑Orotate, ↑citrate, ↑isocitrate, ↑cis-aconitate	Potential abnormalities in arginine, citrulline, nitric oxide	rs7298903, rs3782206, rs2293054
NOS2 *Nitric oxide synthase 2* Inducible nitric oxide synthase (iNOS); considered a reactive free radical involved in neurotransmission along with antimicrobial and antitumoral activities	Manganese	↑Orotate, ↑citrate, ↑isocitrate, ↑cis-aconitate	Potential abnormalities in arginine, citrulline, nitric oxide; responds to antioxdiation	rs2297518, rs2248814, rs2274894
Found in the immune and cardiovascular systems; involved in immune defense against pathogens; maybe induced by lipopolysaccharides and cytokines; commonly found in inflammatory disorders				
NOS3 *Nitric oxide synthase 3* Endothelial nitric oxide synthase (eNOS); involved in vasodilation, vascular smooth muscle relaxation via cGMP-mediated signal transduction pathway; mediates vascular endothelial growth factor (VEGF)-induced angiogenesis in coronary vessels; promotes blood clotting via platelet activation	Manganese	↑Orotate, ↑citrate, ↑isocitrate, ↑cis-aconitate	Potential abnormalities in arginine, citrulline, nitric oxide	rs1800783, rs3918188, rs7830, rs1800779, rs2070744
PAH *Phenylalanine hydroxylase* Converts phenylalanine to tyrosine; associated with PKU	BH4, Fe+3	↑Phenylacetic Acid, (potentially) ↓HVA, ↓VMA	↑Phenylalanine, ↓tyrosine	rs62507347, rs10860936, rs3817446, rs1722387, rs5030858, rs1522305, rs2037639, rs1718301, rs1522296, rs2245360, rs1801153, rs772897, rs1722392, rs1042503, rs5030849, rs1522307, rs11111419, rs10778209, rs1718312
TH *Tyrosine hydroxylase*	BH4, Fe+3	Potentially ↓HVA, ↓VMA	↑Tyrosine, ↓DOPA	rs28934581, rs28934580,
Converts tyrosine to L-DOPA				rs2070762, rs7483056, rs6356
TPH *Tryptophan hydroxylase* Converts tryptophan to 5-HO-RP, a serotonin precursor	BH4, P5P, B2, copper	↑5-HIAA, ↑Glutaric acid	↓Tryptophan	rs623580
DBH *Dopamine beta hydroxylase* Converts dopamine to norepinephrine; may be associated with schizophrenia or depression	Copper, vitamin C	↓VMA, ↑HVA	↑↓Dopamine	rs1611115 rs1108580

(continued)

Table 18.2 (continued)

SNPs	Cofactors	Organic acids	Amino acids/other tests/interventions	rs Numbers
MOA-A *Monoamine oxidase A* Catalyzes the deamination of the amines dopamine, serotonin, epinephrine, norepinephrine Metabolizes the xenobiotic amines: Heterocyclic amines (meat), tyramines and histamine MAO-A preferentially oxidizes serotonin and noradrenaline	FAD	Upregulation: ↓5-HIAA, ↑glutaric acid Downregulation: ↑5-HIAA, ↑glutaric Acid	Potential ↓ in tryptophan, phenylalanine, and tyrosine	Upregulation: rs6323 Downregulation: rs5906883, rs5906957, rs909525, rs9593210, rs2072743
MOA-B *Monoamine oxidase B* Catalyzes the oxidative deamination of biogenic and xenobiotic amines (i.e., histamine and tyramine); part of the metabolism of neuroactive and vasoactive amines in the CNS and peripheral tissues; preferentially oxidizes dopamine; associated with depression	FAD	Upregulation: ↑HVA, ↑VMA, ↑glutaric acid	↓Tyrosine, ↓dopamine	rs1799836, rs10521432, rs6651806
COMT *Catechol-O-methyltransferase* Transfers methyl group from SAM to the catecholamines	Magnesium, SAM	Downregulation: ↓VMA, ↓HVA Upregulation: ↑HVA, ↑VMA	N/A Consider RBC magnesium	rs4680, rs769224, rs4633
Breaks down dopamine, epinephrine, and norepinephrine; transfers a methyl group from SAM to catechols from foods (green tea, potatoes), antioxidants (quercetin), and hormone catechols (estrogen)				
Glutathione				
GSS *Glutathione synthase* Found within the gamma-glutamyl cycle; aids in the production of glutathione	Magnesium	Potential ↑ in pyroglutamate, alpha-hydroxybutyrate and alpha-ketobutyrate	Potential abnormalities in glutamate, cysteine, glycine	rs22273684, rs6088659, rs2236270, rs28936396, rs6060124
GSTT1Del *Glutathione S-transferase theta 1* Conjugates reduced glutathione; has many exogenous and endogenous hydrophobic electrophiles	1200 mg vitamin C/day	Potential ↑ in pyroglutamate, alpha-hydroxybutyrate, and alpha-ketobutyrate	Potential abnormalities in glutamate, cysteine, glycine	rs796052137, rs796052136
GSTM1 *Glutathione-S-transferase Mu 1* Conjugates reduced glutathione; functions in the detoxification of electrophilic compounds including carcinogens, therapeutic drugs, environmental toxins, and products of oxidative stress	Vitamin C	Potential ↑ in pyroglutamate, alpha-hydroxybutyrate, and alpha-ketobutyrate	Potential abnormalities in glutamate, cysteine, glycine	rs2740574, rs4147565, rs4147567, rs4147568, rs1056806, rs12562055, rs2239892

Learning Objectives

- The mucosal immune system as the first line of defense, our homeland security against invading pathogens and diseases.
- The importance of innate immunity in inflammation and autoinflammation.
- The role of adaptive or acquired immunity in health and disease.
- The three tolerance mechanisms that protect the body against immune disorders: The central, oral, and peripheral tolerance mechanisms provide an umbrella of protection against immune disorders.

19.1 Introduction

An immune system is a collection of organs, tissues, cells, and humoral factors that protects a living organism. The immune system shields the body against external harmful influences by developing several levels of protective weapons.

The three major protective layers of the immune system are:

1. The mucosal immune system or surface factors.
2. Innate immunity.
3. Adaptive or acquired immunity.

19.2 The Mucosal Immune System: The First Line of Defense

The mucosal immune system is our body's first line of defense. It allows the absorption of nutrients from our gastrointestinal tract while at the same time maintaining a constant alertness to a large number of harmful pathogens and antigens by using its antenna-like molecules or Toll-like receptors (TLRs) or antibodies such as immunoglobulin A (IgA) or immunoglobulin M (IgM). Using these and other molecules, the mucosal immune system is ready to launch an effective immune response against harmful environmental factors, including infections by viruses, bacteria, parasites, and fungi, as well as toxic chemicals and dietary proteins and peptides [1]. Mucosal immunity protects the epithelial barrier by eliciting pro-inflammatory responses against pathogens or mucosally induced oral tolerance toward food antigens and components of commensal microbiota. Secretory immunoglobulin A (SIgA), which is in all mucous secretions – including milk, saliva, and tears – as well as in GI secretions, the respiratory epithelium, and the genitourinary tract, plays a crucial role in the maintenance of immunological tolerance and protection against allergies and other inflammatory diseases [2]. This is done by inhibiting bacterial and fungal adhesion to the epithelial cells and neutralizing the viruses, antigens, enzymes, and toxins (see Fig. 19.1).

The role of the mucosal immune system in the body's health is so important that an entire society is dedicated to the promotion of its research, advancement, and literary and educational aspects. Part of the mission statement of the Society for Mucosal Immunology (SMI) states: "While general immunologists typically study immune responses in the spleen, lymph nodes or peripheral blood, mucosal immunologists focus on the sites at which most antigens enter – the mucosal surfaces of the gastrointestinal, respiratory, and urogenital tracts … Equally important is the study of the disease states that result when the mucosal immune system's ability to distinguish pathogens from innocuous antigens fails; examples include inflammatory bowel disease and food allergy."

IgA plays a critical role in mucosal immunity. Produced in the mucosal linings, more IgA is generated than all the other antibodies combined. About 3–5 g are secreted into the intestinal lumen daily [3, 4]. It is therefore the most abundant immunoglobulin in all mammals, secreted mostly via the mucous membranes, protecting us against the unceasing assault of pathogens and commensal microbes. The induc-

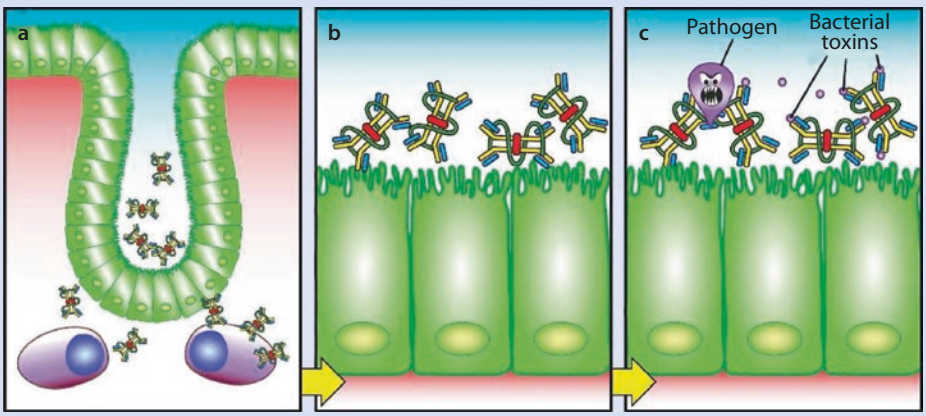

Fig. 19.1 The major antibody isotype present in the lumen of the gut is secretory polymeric IgA. **a** Secretory IgA is synthesized by plasma cells in the lamina propria and transported into the lumen of the gut through epithelial cells at the base of the crypts. **b** Polymeric IgA binds to the mucus layer overlying the gut epithelium and **c** acts as an antigen-specific barrier to the pathogens and toxins in the gut lumen

tion of IgA occurs via both T-dependent and T-independent mechanisms. After dendritic cells have sampled a tiny fraction of the intestinal antigens, IgA specifically is produced against the commensal microbes and food antigens.

In one study [5], IgA and IgG antigens specific to ovalbumin, β-lactoglobulin, or gliadin were measured in serum, saliva, colostrum, and breast milk from 40 healthy breastfeeding women, and specific IgA reactivity was found in all the samples analyzed. Levels were found to be highest in colostrum and milk, followed by saliva, and then in serum. Despite inclusion in the testing of three unrelated food antigens (gliadin, albumin, lactoglobulin), a correlation between the levels of specific IgA was found in the saliva, colostrum, and milk samples of all 40 subjects [5].

In individuals with IgA deficiency, a compensatory increase in secretory IgM has also been detected [6]. These findings together support the importance of measuring IgA and IgM antibodies against different components of gut microbiome and food antigens.

Furthermore, the increased production of IgA antibody in the blood, which is measured against food antigens and bacterial toxins, is the spillover from increased mucosal IgA production. In this process, naïve B cells generated in the bone marrow migrate to the inductive sites of mucosal immunity represented by the gut-associated lymphoid tissues (GALT or Peyer's patches; lymphoid follicles of the large bowel) or bronchus-associated lymphoid tissues, where they are stimulated by antigen-presenting cells (APCs) and cognate T-helper cells. Antigen-stimulated B and T cells migrate out through the draining lymph nodes and lymphatics and enter the bloodstream. During this process, a subset of these cells remains in the blood in the form of memory cells that recognize food antigens. The stimulated cells finally relocate or "home in" to the effector sites (including the lamina propria) of the gastrointestinal, respiratory, and genital tracts and various endocrine glands, where they secrete a significant amount of IgA antibody. This spillover from IgA production in saliva can be detected in the blood using different immunological assays.

Although production of IgA antibody in the secretion is considered protective, in the case of oral tolerance failure, the overproduction of IgA against food antigens and bacterial toxins may result in IgA immune complex formation. This may be followed by the production of pro-inflammatory cytokines, all of which can lead to increased intestinal permeability and increased antigen exposure. This will then lead to increased IgA and IgM production against dietary proteins and bacterial antigens in the blood [7, 8].

19.2.1 Intestinal Permeability to Large Macromolecules

A number of conditions and environmental triggers can result in damage to the intestinal barrier and increased permeability to large macromolecules, leading to the loss of mucosal immune tolerance and the passage of dietary proteins into the submucosa and regional lymph nodes and into the circulation. The ensuing immune response against these invading antigens results in the formation of polymeric IgA and immune complexes, which bind to the mucosal layer to protect against greater damage. However, these immune complexes, along with inflammatory cytokines, can lead to further increased gut permeability and to the entry of dietary proteins and peptides into the bloodstream and formation of antibodies against these antigens. Circulating memory B lymphocytes that have previously been exposed to these antigens upon repeated exposure to the same antigen(s) will cause the formation of plasma cells with J chains to produce antibodies in the blood in a much shorter period of time than the primary immune response. A J chain is a protein component that acts like a "glue" in IgA and IgM antibodies. When these antigens and peptides are presented to APCs, T cells, and B cells for the first time, the plasma cell formation can result in the production of both IgG and IgA against dietary proteins and peptides in the blood within 15 days. If these antigens share homology with different tissue antigens, they can initiate an autoimmune disease in different organs, such as the kidneys, liver, brain, skeletal muscles, and others [9, 10].

19.2.2 Diagnostic Features of the Mucosal Immune System

The importance of measuring the total and specific SIgA is well established in different disorders.

For example, testing for SIgA helps in determining:

- If the mucosal immune system is in a healthy and balanced state. Normal levels of SIgA may indicate a healthy mucosal immune system; very high or low SIgA may indicate inflammation, autoimmunity, and immunodeficiency.
- Elevated total SIgA with elevation of IgA or IgM antibodies against oral pathogens may indicate chronic infection in the oral cavity.
- Elevated total SIgA with elevation of IgA or IgM antibodies against bacterial cytotoxins and tight junction proteins may indicate intestinal barrier dysfunction to large molecules, irritable bowel syndrome, and small intestinal bacterial overgrowth (SIBO).
- Elevated total SIgA with elevation in IgA or IgM antibodies against a variety of food antigens may indicate breakdown in oral tolerance, enhanced intestinal permeability, food immune reaction, and possibly autoimmunities.
- Elevated total SIgA with elevation in IgA or IgM antibodies against gliadin and transglutaminase-2, actomyosin, *Saccharomyces cerevisiae,* and/or calprotectin may indicate the possibility of non-celiac gluten sensitivity (NCGS), celiac disease (CD), and its overlap with Crohn's disease and ulcerative colitis.
- Elevated total SIgA with elevation in IgA and IgM antibodies against different parasitic antigens may indicate parasitic infection [11–20].

This is why the textbook of Food Allergy and Intolerance [21] states that: "Mucosal production of IgA and IgM antibodies to dietary antigens, and particularly to gliadin, appears to be an early event in the gluten-sensitive enteropathy but does not initially cause a flat lesion."

19.3 An Innate Immune System

The mucosal immune system of higher mammals is covered by a single layer of epithelium, which secretes antimicrobial peptide and is topped by a thick layer of mucus. This system is fortified by both innate and adaptive immune responses to protect the host against the harsh environment of bacteria, toxins, antigens, and a variety of food components that varies from person to person. This interrelationship between the mucosal immune system and gut bacteria is bidirectional. For example, bacteria flourish on food components, such as carbohydrates, proteins, and vitamins, and in return reward the microbiota by developing oral tolerance and natural immunity through regulatory T cells (CD4+ cD25+) and regulatory cytokines (TGF-β and IL-10). Moreover, the host microbiota influences the development and maturation of lymphoid cells involved in mucosal immunity [22–24].

The innate immune system acts as the "first responders" against pathogens such as bacteria, viruses, fungi, and protozoans. This system is not unique to mammals; even invertebrates possess the ability to protect themselves against invaders. From an evolutionary point of view, this ancient mechanism was developed to protect multicellular organisms. However, starting with the fish, and going through amphibians and birds and all the way to mammals, the innate immune system provides this frontline barrier or defense. It very wisely stops the enemy to provide the required time for action by the adaptive immune system and the development of specific antibodies against the pathogens, which requires about 2 weeks [25]. Think of it as the frontline soldiers fighting a heroic holding action against the assaulting forces to give their reinforcements enough time to prepare the necessary weapons and bring them to the battle.

The innate immune system in the mucous membranes consists of several physiologic, anatomic, and cellular components. The anatomical aspects include mucosal surfaces of the skin, lungs, mammary, and gastrointestinal and urogenital tracts. Secretion of hydrochloric acid and digestive enzymes is a major physiologic function that – in collaboration with gut barrier structures – prevents the entry of food antigens, bacterial toxins, and whole pathogens into the body. Complement proteins and some cytokines are also considered components of innate immunity. Innate immunity as a whole is a nonselective, nonspecific immune system and does not modify itself based on the type of invaders. For example, most food antigens are digested by digestive enzymes and, other than *H. pylori,* most pathogens cannot withstand the low pH of the stomach.

However, the cellular component of innate immunity is more selective and constantly modifies itself to efficiently combat the enemy. The cellular component consists of monocytes, dendritic cells, macrophages, innate lymphoid cells, natural killer cells, mast cells, basophils, neutrophils, eosinophils, epithelial cells, and paneth cells [26].

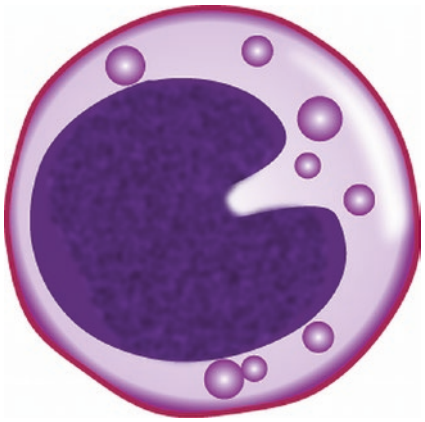

Fig. 19.2 Monocytes

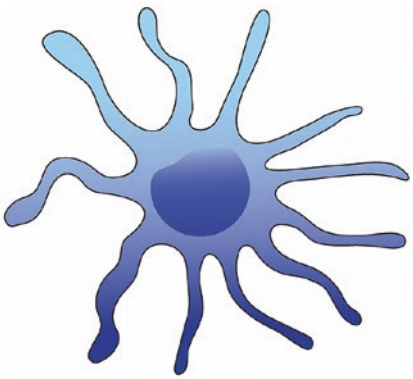

Fig. 19.3 Dendritic cell

Monocytes are produced by the bone marrow (Fig. 19.2). The largest type of leukocyte, they are recognizable by their distinct kidney-shaped nucleus. They circulate in the bloodstream for 1–3 days before moving into the tissues throughout the body and differentiating into macrophages and myeloid lineage dendritic cells. Half of the body's monocytes remain stored in the spleen as a reserve. Monocytes and their macrophage and dendritic cell descendants have three main functions in the immune system: phagocytosis, antigen presentation, and cytokine production.

Dendritic cells (DCs) are antigen-presenting cells (APCs) that act as messengers between the innate and adaptive immune systems (Fig. 19.3). Their main function is to process antigenic material and present it on their cell surfaces to T cells. They can be found in the tissues that come in contact with the external environment, such as the skin, the inside of the nose, the lungs, the stomach, the intestines, and, in an immature state, in the blood. When activated, they migrate to the lymph nodes where they interact with B cells and T cells to craft the adaptive immune response. They grow the projections or dendrites that give them their name.

Macrophages are the junkyard dogs of the human body (Fig. 19.4). They are found in virtually all tissues, where

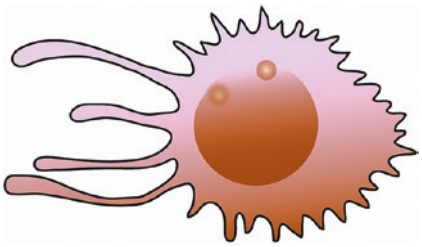

Fig. 19.4 Macrophage

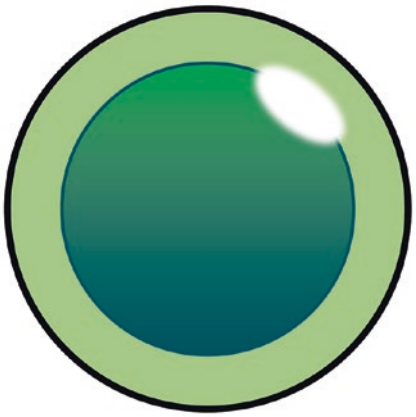

Fig. 19.5 Innate lymphoid cell

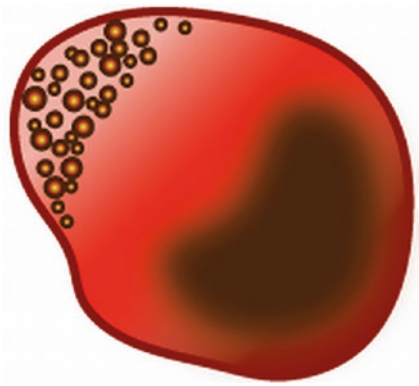

Fig. 19.6 NK cell

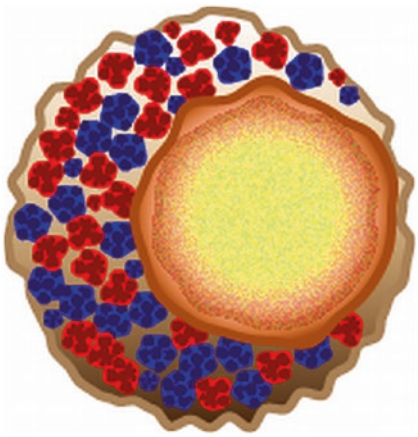

Fig. 19.7 Mast cell

they patrol for potential pathogens such as cellular debris, foreign substances, microbes, cancer cells, and anything else that they don't identify as a healthy body cell. When they find an object that they identify as alien or harmful, they become true to their name (which means "big eater"), engulfing and digesting the offending antigen and presenting the digested bits to T cells. They have various forms and various names to go with them. M1 macrophages encourage inflammation, whereas M2 macrophages decrease inflammation and encourage tissue repair. Macrophages can also decrease immune reactions through the release of cytokines.

Innate lymphoid cells (ILCs) are a group of innate immune cells derived from a common lymphoid progenitor (CLP) (Fig. 19.5). They are identified by the absence of an antigen-specific B- or T-cell receptor because they lack the recombination-activating gene (RAG). They have various physiological functions and have an important role in protective immunity and the regulation of homeostasis and inflammation. Their dysregulation can lead to immune disorders and even autoimmune disease.

Natural killer cells (NK cells) are a type of cytotoxic lymphocyte (Fig. 19.6). Their main function is to kill tumor cells and virally infected cells. They are to the innate immune system what cytotoxic T cells are to the adaptive immune system. Normally, protective immune cells do their job by detecting the major histocompatibility complex (MHC) presented on infected cell surfaces, which cause them to trigger cytokine release and cause lysis or apoptosis. NK cells are unique in that they have the ability to recognize stressed cells even in the absence of antibodies or MHC. This gives them a much faster reaction time and makes them the only protective immune cell that can detect and destroy harmful cells that are missing MHC markers. They use perforin and granzyme B to kill their targets.

Mast cells (mastocytes, labrocytes) are granulocytes derived from the myeloid stem cell (Fig. 19.7). They contain many granules rich in histamine and heparin. Best known for their role in allergies, mast cells can bind to the fragment crystallizable (Fc) region of IgE, causing them to release histamine and other inflammatory mediators. However, they also play an important protective role and are critically involved in wound healing, angiogenesis, immune tolerance, anti-pathogen defense, and the blood-brain barrier function.

Basophils are the least common but largest of the granulocytes (Fig. 19.8). They are responsible for inflammatory reactions during immune response and for the formation of acute and chronic allergic diseases such as anaphylaxis, asthma, atopic dermatitis, and hay fever. On the protective side, they can perform phagocytosis and produce histamine and serotonin to reduce inflammation and heparin to prevent blood clotting. They were once thought to be mast cell precursors, but no longer. They have a distinct two-lobed nucleus surrounded by cytoplasmic granules.

Neutrophils or neutrocytes are the most abundant of the granulocytes and are an essential part of the innate immune

Fig. 19.8 Basophil

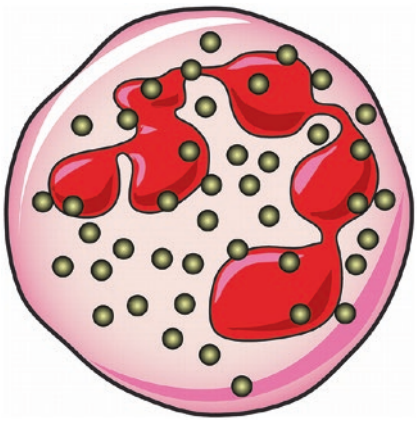

Fig. 19.9 Neutrophil

system (Fig. 19.9). Formed from stem cells in the bone marrow, they are short-lived and highly motile and can enter parts of tissue that other cells or molecules can't. During the starting phase of inflammation, neutrophils are one of the first responders to migrate toward the trouble site, reaching it within minutes following the causative trauma. They are the predominant cells in pus and account for its whitish/yellowish appearance. They are part of the polymorphonuclear cell family along with the mast cells, basophils, and eosinophils.

Eosinophils are one of the immune system's components responsible for combating multicellular parasites and certain infections in vertebrates (Fig. 19.10). They are granulocytes that develop during hematopoiesis in the bone marrow before migrating into blood. Like mast cells and basophils, they control mechanisms associated with asthma and allergy. Their granules contain many chemical mediators that are toxic to both parasite and host tissues. They are unique granulocytes in that they can survive for extended periods of time after maturation, persisting in the circulation for 8–12 hours and in tissue an additional 8–12 days without stimulation.

Epithelial cells (ECs) are one of the most important cells found in the human body. They are the first type of cells to encounter external stimuli (Fig. 19.11). They line the cavities and surfaces of blood vessels and organs throughout the

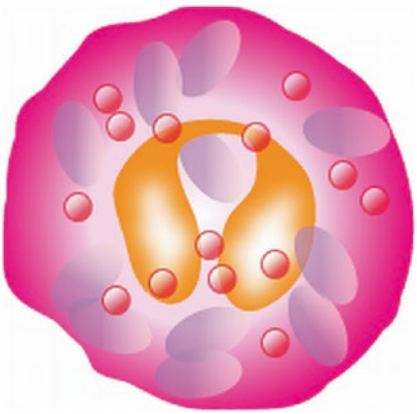

Fig. 19.10 Eosinophil

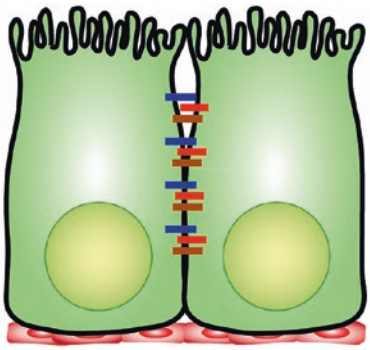

Fig. 19.11 Epithelial cells

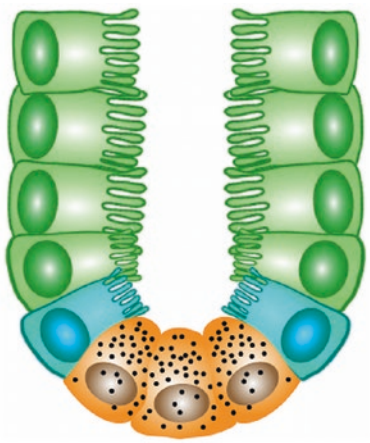

Fig. 19.12 Paneth cells

body. Epithelial cells come in different shapes, depending on where in the body they're found; the three basic shapes are called squamous, cuboidal, and columnar. Structurally, ECs rest on a basement membrane and are interconnected by cell junctions. The functions of ECs include secretion, selective absorption, protection, transcellular transport, sensing, and maintaining the integrity of the gut barriers.

Paneth cells are found at the bottom of the intestinal crypts in the small intestine (Fig. 19.12). They are the key effectors of innate mucosal defense, producing large amounts

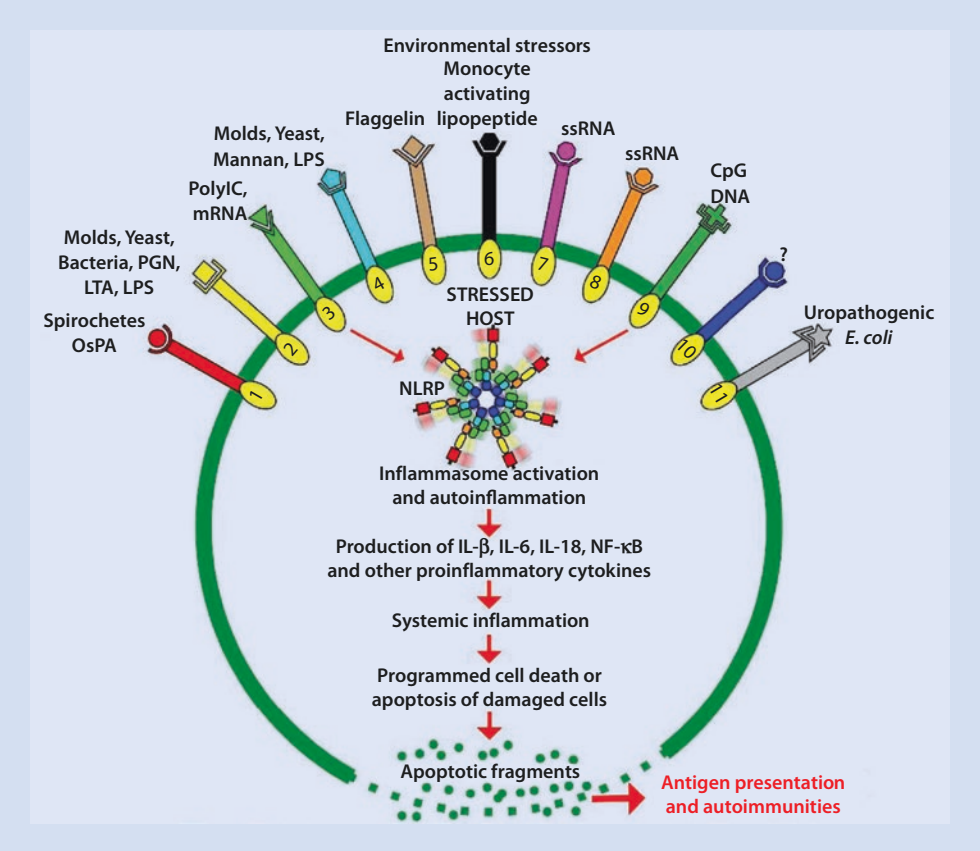

Fig. 19.13 How mammalian cells via the recognition of different patterns detect the presence of invading triggers. Environmental triggers bind to TLRs (1–11) present on the surface of macrophages and neutrophils. This initiates activation of inflammasomes and initiation of the autoinflammatory process. Inflammasomes activate the inflammatory cytokines, causing systemic inflammation and induction of programmed cell death of tissues that were affected by environmental stressors. PGN peptidoglycan, LTA lipoteichoic acid, LPS lipopolysaccharide, OsPA outer surface protein A

of α-defensins and other antimicrobial peptides, such as lysozymes and secretory phospholipase A2 (sPLA2). These substances are stored in secretory granules and released into the intestinal lumen upon stimulation with bacterial antigens such as lipopolysaccharide (LPS) and muramyl dipeptide (MDP).

This cellular component of innate immunity identifies foreign materials by the previously mentioned antenna-like structures known as TLRs. Because pathogens contain molecules such as lipoteichoic acid, lipopolysaccharides (LPS), and others which are not found on mammalian cells, the innate systems are able to recognize and detect the invading pathogens. These molecules are called pathogen-associated molecular patterns (PAMPs). The binding of PAMPs on the pathogens to TLRs on macrophages and neutrophils initiates the killing mechanism. An additional component of the innate system is an intracellular component known as the *inflammasome*. Inflammasomes are NOD-like receptors (NLRPs) which detect intracellular PAMPs after phagocytosis. This causes the release of proinflammatory cytokines from the activated cells and activation of the inflammasome.

The cytokines plus activated inflammasomes induce the apoptosis and death of infected cells. This way, cells that are heavily infected with pathogens are cleared from the system [27] (see ◘ Fig. 19.13). Overall, the inflammatory reaction is divided into exogenous and endogenous inflammation, both of which are associated with diseases:

The exogenous factors that induce inflammation-associated diseases are:

- Dietary components: gluten, casein, lectins, agglutinins, other food antigens, glucose, cholesterol.
- Toxic chemical exposure: drugs, smoking, pollution, plasticizer, adjuvants, pesticides, herbicides.
- Infections and their antigens: bacteria, viruses, yeasts, molds, parasites, spirochetes.

The endogenous inflammation includes autoinflammation and autoimmune inflammation. Inflammation underlies a wide variety of physiological and pathological conditions.

- Autoinflammatory diseases are diseases of innate immunity.
- Autoimmune diseases are diseases of both innate and adaptive immunity.

Inflammation is the immune system's natural response to infections, tissue damage, or metabolic disorders. The purpose of the inflammatory activity is to kill pathogenic microbes, repair injured tissue, and remove harmful metabolite deposits. Normally, tissue homeostasis is restored once the inflammation has done its work and run its course. However, the incomplete resolution of inflammatory responses along with chronic effects of immune stressors is known to be an important trigger of tissue pathology in numerous diseases, such as atherosclerosis, rheumatoid arthritis, psoriasis, and diabetes. When this happens in the brain as a result of astro-

cyte activation and astrocyte reaction to infectious agents (amyloid plaque formation), it is called neuroinflammation. Neuroinflammation could result in a decline of neurologic function. It accompanies a variety of neurodegenerative diseases, such as dementia, Alzheimer's, or Parkinson's; it has become increasingly evident that in many, or perhaps even all of these, neuroinflammation is not only a consequence but could also be a pathologic trigger. In many neurodegenerative pathologies, various triggers of inflammation are found and can actually be used as biomarkers for the particular disease. Therefore, rather than a late consequence, immune activation could be an early cause in neurodegenerative diseases; this suggests that anti-inflammatory therapies could be a promising treatment approach [28].

Both inflammatory and autoimmune diseases are very complex, and for their investigation, high-throughput methods are needed. For example, C-reactive protein (CRP) or sedimentation rate is not sensitive enough, but mediators such as IL-1β, TNF-α, IL-6, NF-κB, and other cytokines are very sensitive biomarkers. Furthermore, the study of the function of effectors such as T cells, B cells, NK cells, macrophages, neutrophils, epithelial cells, and endothelial cells helps in the investigation of the pathways involved in the physiological role of inflammatory pathophysiology [29]. The exact endogenous stimuli that induce autoinflammatory disorders is not known yet, but six different molecular mechanisms in the development of autoinflammatory diseases have been described [30].

1. *IL-1β activation disorders or inflammasomopathies.* The inflammasomes or NLRPs are the guardians of the body and are part of the inflammation engines. These engine-like materials are involved in the proteolytic activation of pro-inflammatory cytokines such as IL-1β and IL-18. One such disorder in which inflammasome activation is involved is gout, which could be initiated by dietary components (e.g., chicken), bacteria (such as *S. aureus*), viral DNA, toxic chemicals, skin irritants, UV, adjuvants, or food additives [27–30].
2. *NF-κB activation syndromes.* Loss-of-function mutations can cause dysfunctions in NF-κB's response to intracellular microbial products, leading to pro-inflammatory diseases.
3. *Protein misfolding disorder.* These mishaps in the cells of the innate immune system can have biological consequences. Generally speaking, misfolding disorders can trigger the wrong responses and cause inappropriate cytokine secretions. For instance, in TNF receptor-associated periodic syndrome (TRAPS), missense substitutions in the p55 TNF receptor lead to misfolding and ligand-independent activation of kinases and aberrant cytokine production.
4. *Complement regulatory diseases.* Complements are key components of innate immunity, and deficiencies in complement regulatory factors can lead to a classical autoimmune lupus-like picture, producing an autoinflammatory phenotype such as age-related macular degeneration and atypical hemolytic uremic syndrome.
5. *Disturbance in cytokine signaling.* Given the importance of cytokines in immunity, it is not surprising that erroneous cytokine signaling can lead to autoimmune disorders. One such example is cherubism, a relatively newly recognized autoinflammatory disorder of the bone. It is caused by mutations in an SH3-binding protein, which in animal models leads to heightened responsiveness to the cytokines M-CSF (macrophage colony-stimulating factor) and RANKL (receptor activator of NF-kappaB ligand), and increased osteoclastogenesis.
6. *Macrophage activation syndrome*. This syndrome is a common factor among many autoinflammatory disorders, such as Chediak-Higashi syndrome, familial hemophagocytic lymphohistiocytosis, and atherosclerosis. Among its causes are loss-of-function lesions in the adaptive immune system, the activation of effector cells in the innate immune system, and the elaboration of a pro-inflammatory cytokine milieu.

19.3.1 Diagnostic Features of the Innate Immune System

- Macrophage/monocyte function
- Neutrophil function (immune complexes), CD116/CD18
- Acute phase proteins and inflammation: CRP, serum amyloid A, fibrinogen, other clotting factors, vasoactive amines such as histamine and serotonin
- Complement hemolytic activity and complement components
- Pro-inflammatory cytokines and proteins: IL-1β, TNF-α, IL-6, NF-κB, MCP-1, IL-17A–IL-17F, INF-γ
- Natural killer cytotoxic activity

19.4 Acquired or Adaptive Immunity

The adaptive immune system is known as the second arm of immunity. It is characterized by cellular immune reaction against different antigens and production of specific antibodies against them. During this process, the pathogens, because of their large size, are phagocytosed and digested into very small pieces by macrophages and dendritic cells. These digested pieces of pathogens, which are named antigens, are then presented on the surfaces of antigen-presenting cells (APCs) to T-helper cells (Th cells) (see Fig. 19.14). The Th cells secrete different cytokines to communicate with B cells, stimulating them to go through blastogenesis, B-cell expansion, plasma cell formation, and the production of IgM followed by IgG antibodies.

Simultaneously, Th cells in response to interleukin-2 will develop into cytotoxic T lymphocytes, which express antibodies on their surface, guiding them to go after cells infected with pathogens, such as a virus. This way, the body gets rid of both pathogens and cells infected with pathogens [26].

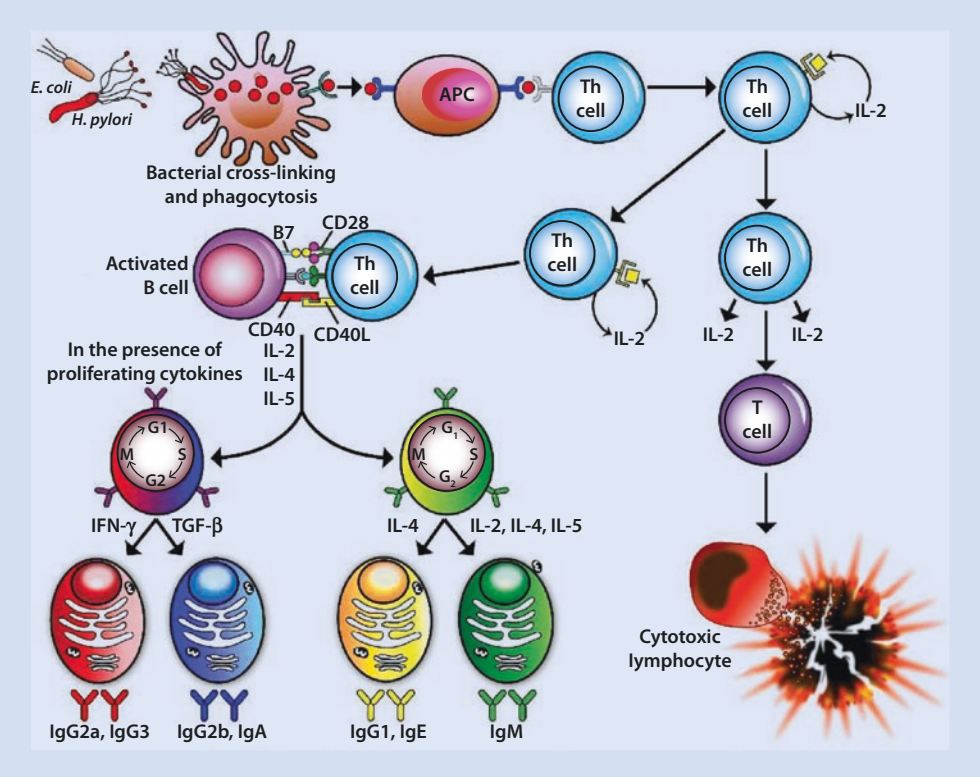

Fig. 19.14 The adaptive immune system. Invading pathogens are phagocytosed into smaller manageable pieces and presented by APCs to Th cells, causing them to secrete cytokines and undergo differentiation and other processes involved in immune response, including the production of different phenotypes of immunoglobulin antibodies

19.4.1 Primary and Secondary Immune Response

When an antigen comes into contact with the immune system for the first time, our body's response is to activate the *primary immune response*. At this time, the immune system still has to learn all it can about the invading pathogen so it can make the proper antibody against it. The lag time to form the response may take a while, from 4 to 7 days to sometimes even weeks or months, so that immunity takes longer to establish. The "first responders" to this antigenic attack are the *effector cells*, relatively short-lived cells designed for an initial response. Effector B cells or plasma cells secrete antibodies; effector T cells include cytotoxic T cells and helper T cells, which carry out cell-mediated responses. The first antibodies produced are mainly IgM, although small amounts of IgG also occur (see Fig. 19.15). The amount of antibody produced depends on the antigen but is typically low. The level of antibody peaks in 14 days and declines rapidly. The affinity of the antibody produced at this time for its antigen is lower. This primary antibody response appears mainly in the lymph nodes and spleen.

The *secondary immune response* is launched upon the immune system's second and subsequent exposure to the same previously encountered antigen. When the immune system first encounters the invading antigen, some of the responding naïve B cells and T cells become *memory cells*. Memory T cells and B cells are immune cells that are longer-lived than the other initial responder cells. They remain in the body after initial infection and retain a memory of the

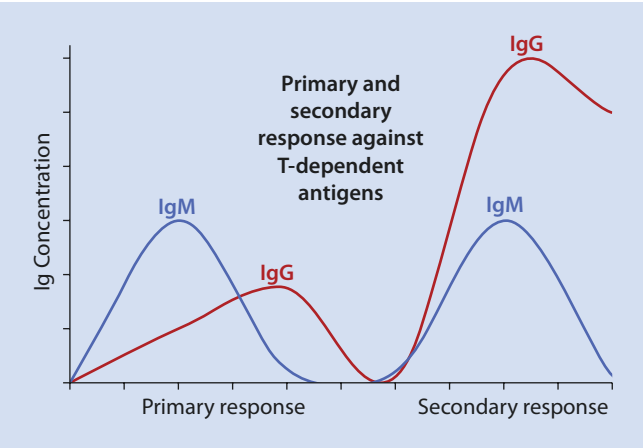

Fig. 19.15 IgM and IgG response. Th cells produce an immune response first in the form of IgM antibodies and then IgG antibodies

strategy used to defeat the pathogen the first time it was encountered. Once the immune system recognizes its old enemy, it fires up the memory cells for a fast and powerful secondary immune response. Thus, the response time is much shorter, from 1 to 4 days. This means that immunity takes a shorter time to establish. Primarily IgG antibody is produced, with some small amounts of IgM occasionally occurring as well (see Fig. 19.15). IgA and IgE are also produced. Usually 100–1000 times more antibodies are produced in the secondary response than in the first. The level of antibody peaks in 3–5 days and remains high for a longer period. The affinity of the antibody for its antigen is much

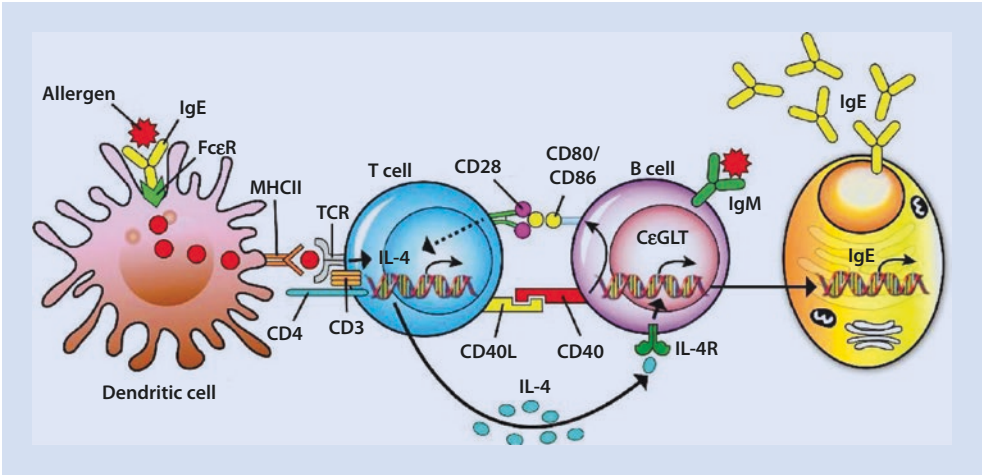

Fig. 19.16 Production of allergen-specific IgE by receptor upregulation in collaboration with dendritic cell, T cell, B cell, and plasma cell. Allergens are taken up by DCs and presented to T cells, stimulating the upregulation of CD40 ligand expression. This in turn stimulates the expression of CD80/CD86, which binds to CD28 and leads to the production of more IL-4. The IL-4 binds to the IL-4 receptor on B cells and activates the transcription factor, causing class-switch to IgE and the production of significant amounts of IgE, releasing the mediators involved in classical allergy

greater and therefore more effective. The secondary immune response appears mainly in the bone marrow, followed by the spleen and lymph nodes.

Antibodies or immunoglobulins (Ig) take a variety of forms or isotypes. The most common Ig isotypes are IgG, IgA, IgM, and IgE, or the easily remembered acronym GAME. IgM, known as acute antibodies, are the first to arrive. The IgM antibodies are relatively low-affinity, produced rapidly in order to control infection. IgG is the more specific isotype, consisting of IgG_1, IgG_2, IgG_3, and IgG_4 subclasses. For the production of IgG, additional time is required, and it appears in the blood when IgM levels are in the process of decline. IgG antibody levels peak at about 30 days and stay in the body for several months in order to protect it from future possible infections (Fig. 19.15). The production of IgG, IgA, IgM, and IgE depends on the cytokine environment. For example, after collaboration between Th cells and B cells in the presence of proliferating cytokines, such as IL-2, IL-4, and IL-5, and of differentiation cytokines IFN-α and TGF-β, the plasma cells produce IgG_2, IgG_3, and IgA. With the help of IL-2, IL-4, and IL-5, the activated cells may produce IgM, and in the presence of Th2 cytokine IL-4, the plasma cells may produce IgG and IgE. The production of the IgE isotype of antibody, which is involved in allergy, depends on the cellular interactions that are important for IgE class switch recombination. During this process, the uptake of allergens such as peanut or house dust mites by dendritic cells allows antigenic presentation to the T cells. Stimulation of specific helper cells by these antigens or allergens leads to the production of Th2 cytokines (IL-4) and the upregulation of CD40 ligand expression by the T cells.

Binding of CD40L to CD40 on the B-cell membrane upregulates the expression of costimulatory molecules and CD80/CD86, which binds to CD28 receptor to stimulate further production of IL-4. This binding of CD 40 L to CD40 and CD28 to CD80/CD86, and the production of more IL-4, results in IL-4 binding to IL-4 receptor on B cells, signaling the activation of the transcription factor in B cells. Enhancement of transcription factor and activation-induced cytidine deaminase causes IgE class-switch recombination and the production of significant amounts of IgE (see Fig. 19.16). The binding of IgE to IgE receptor on mast cells and its bridging by the allergens result in the release of mediators that are involved in the classical allergy symptomologies [26].

19.4.2 IgE and Allergic Reactions

Distinctions should be made between sensitivities and allergies. True allergic reactions are triggered when allergens cross-link preformed IgE bound to the high-affinity receptor FcεRI on mast cells. Mast cells line the body surfaces and serve to alert the immune system to local infection. Once activated, they induce inflammatory reactions by secreting chemical mediators stored in preformed granules and by synthesizing leukotrienes and cytokines after activation occurs. In allergy, they provoke very unpleasant reactions to innocuous antigens that are not associated with invading pathogens that need to be expelled. The consequences of IgE-mediated mast-cell activation depend on the dose of antigen and its route of entry, with symptoms ranging from the irritating sniffles of hay fever when pollen is inhaled to the life-threatening circulatory collapse that occurs in systemic anaphylaxis. A more sustained inflammation known as the late-phase response follows the immediate allergic reaction caused by mast-cell degranulation. This late response involves the recruitment of other effector cells, notably Th2 lymphocytes, eosinophils, and basophils, which contribute significantly to the immunopathology of an allergic response.

Most antibodies are found in body fluids and engage effector cells, through receptors specific for the Fc constant

regions, only after binding to a specific antigen through the antibody variable regions. IgE, however, is an exception, as it is captured by the high-affinity Fcε receptor in the absence of bound antigen. This means that IgE is mostly found fixed in the tissues on mast cells that bear the Fcε receptor, as well as on activated eosinophils and circulating basophils. The ligation of cell-bound IgE antibody by specific antigen triggers the activation of these cells at the site of antigen entry into the tissues. The release of inflammatory lipid mediators, cytokines, and chemokines at the sites of IgE-triggered reactions results in the recruitment of eosinophils and basophils to augment the type I response.

When the humoral and cellular components of adaptive immune response fail, the results could be allergies and autoimmunities.

19.4.3 Diagnostic Features of the Adaptive Immune System

- Immunoglobulins and immunoglobulin subclasses
- Immune response to vaccination or antigenic challenge
- Antibody titers, ANA, RF, ssDNA, and other tissue-specific antibodies against self-antigens (multiple autoimmune reactivity screen)
- Lymphocyte subpopulation including regulatory T cell
- T- and B-cell function (antigen/mitogen stimulation)
- Monitoring cell death (apoptosis)
- Cytokine production after antigen challenges

19.5 The Three Major Mechanisms of Protection against Autoimmunity

Oral tolerance, central tolerance, and peripheral tolerance are the three major mechanisms that protect the body against autoimmunities. Breakdown in any of these three mechanisms, especially failure in oral tolerance, can result in food immune reaction and associated autoimmunities [31].

19.5.1 Oral Tolerance

The gut mucosal immune system has to keep an intricate immune homeostasis by maintaining tolerance to harmless or even beneficial molecules in the gut while mounting an effective immune defense against pathogens [32]. The unresponsiveness to food antigens with subsequent down-regulation of systemic immune response is what is characterized as oral tolerance. The failure of this system results in immune reactivities to the food we eat, sometimes with life-threatening consequences such as allergies and autoimmunities [32]. The revolutionary developments in the fields of mucosal immunology and microbiology of the gut in recent years are the best indication of the importance of commensal flora, gut barriers, and oral tolerance to human health and disease. The specific mechanisms of action that separate tolerance from effective immunity against various food and bacterial antigens have yet to be fully explored and are the subject of ongoing research.

When these different mechanisms of action fail to control ingested antigens, the first result can be a breakdown in tolerance to soluble antigens, which then triggers active secretory and systemic immune responses against food antigens. Indeed, individuals in whom the immune exclusion mechanism does not function may experience chronic hyperabsorption of macromolecules and the tendency to develop autoantibodies and even autoimmune disease [33, 34].

19.5.1.1 Exclusion of Various Antigens by Secretory IgA and IgM Antibodies to Modulate or Inhibit Colonization of Bacteria and Yeast and Dampen Penetration by Dangerous Soluble Luminal Agents

A child at birth has almost no protective immune system other than passive immunity and maternal transfer of IgG against various food antigens and infectious agents. Although born practically germ-free and with no microbiota in the gastrointestinal (GI) tract, the child's mucosae are immediately assaulted after birth by a motley horde of microorganisms originating, first, from the mother; secondly, from the air in the delivery room and the doctor and nurses present; thirdly, from breast milk or baby formula; and, lastly, from exposure to various food antigens upon the introduction of solid food. This is why the mucosal immune system has evolved into the two arms of defense, innate immunity and adaptive immunity, to handle these challenges [35].

Maternally acquired immunity is essential for the survival of newborns until endogenous immunity develops. These exogenous antibodies are acquired both prenatally through transplacental transfer and postnatally via breast-feeding and colostrum [36]. In fact, when breast-fed infants were compared with formula-fed babies, a more rapid increase in SIgA1, SIgA2, and total salivary IgA was observed during the first 6 months [37]. Furthermore, breast-fed infants also produce higher levels of SIgA in urine than formula-fed infants. Therefore, the importance of infant feeding practices cannot be underestimated, since there is significant association between feeding patterns, bacterial colonization, and immunological maturation – in particular with respect to IgA- and IgM-containing plasma cells in the gut lamina propria. This is why intravenous-fed fully developed infants lack these IgA- and IgM-producing plasma cells in their gut tissue, while the orally fed individuals have adult proportions of these immunocytes [38]. Furthermore, the initial bacterial colonization and subsequent antigenic challenge in the GI tract differ between breast-fed and formula-fed infants. In addition to providing secretory IgA and IgM, breast milk reinforces mucosal defenses by delivering antigens, immune complexes, regulatory cytokines, growth factors, and peribiotics such as

oligosaccharides that promote the proliferation of friendly bacteria, which are part of the neonatal intestinal microbiota. This could be an explanation for the protective role breastfeeding plays when inflammatory bowel disease develops later in life. This emphasizes the impact of perinatal immune development, in particular IgA and IgM antibodies, on mucosal homeostasis and chronic inflammation [39–41].

Oral tolerance to dietary proteins is crucial to prevent the development of food immune reactivity. The mode of antigen uptake in the gut and different regulatory immune cells plays a role in its maintenance. In addition to the intestinal epithelial cells acting as nonprofessional APCS, DCs, CD8+ cells, and a variety of regulatory CD4+ cells – namely, TR1, Th3, or CD4+ CD25+ cells – play an important role in maintaining oral tolerance to low doses of antigen through suppression of immune responses. Other mechanisms are important in response to high antigen doses, including induction of lymphocyte anergy or deletion.

This induction of oral tolerance to soluble antigens is not limited only to the intestinal mucosa but can involve the entire body. The explanation for this is that through oral exposure, an antigen can gain access to the blood via the lymph. Indeed, food protein can be detected in the blood of mice and humans soon after eating [42]. This entry of undegraded food proteins into the circulation at low levels is a normal process, but in the presence of inactive enzymes or resistance of some dietary proteins to degradation, the level of dietary proteins in the blood is enhanced. Of course, this presence of food antigen in the blood does not go unnoticed by the immune system. If the antigen is taken up by the blood antigen-presenting cell, the result could be IgG or IgA antibody production.

19.5.1.2 Factors Involved in the Induction or Disturbance of Oral Tolerance

Several factors affect the induction of oral tolerance to a dietary antigen. Some are antigen-related, namely, the doses and nature of the antigen. Other factors are inherent to the host, including age, genetics, intestinal flora, diet, medication, and more. Epidemiological studies have revealed that there is one factor of particular importance in the development of oral tolerance [43, 44]. This is the period surrounding a child's birth. Early-life exposure to environmental triggers before birth (through the mother), during birth, and after birth acts as a priming period that shapes the future enteric microbiota and the innate and adaptive immune systems, which reach a lasting homeostatic equilibrium shortly after a child is born [43, 44]. This period could be called *the neonatal window of opportunity* (see ◘ Fig. 19.17).

19.5.1.3 Breach in Oral Tolerance and Its Association with Food Immune Reactivities

Oral tolerance is induced by multiple cellular and molecular processes to ensure lack of immune reactivity to harmless intestinally derived antigens both in the mucosa and in the systemic immune system [45]. Together, mucosal and

◘ **Fig. 19.17** The neonatal window of opportunity. Early-life exposure to environmental triggers before birth, during birth, and after birth sets the foundations of the immune system to come

circulatory-induced tolerance appears to prevent intestinal disorders such as inflammatory bowel disease, food immune reactivity, and organ-specific and nonspecific autoimmunities. This process is carried out by a very special population of dendritic cells found in the microenvironment of mesenteric lymph nodes. The presence of antigen-specific T cells and nodes and cytokines such as TGF-β and IL-10 induces the generation and differentiation of these DCs into FOXP3+ regulatory T cells (Tregs). These committed Tregs home back to the intestinal lamina propria, where some of them may exit from the mucosa via the lymphatic system or bloodstream and disseminate throughout the immune system, promoting systemic oral tolerance [45]. The ability of oral tolerance to maintain an inhibitory environment by the Treg cells and the production of noninflammatory IgA against both dietary proteins and microbiota can prevent hyperimmune reactivities in the mucosa and in circulation [46, 47]. The perinatal period is therefore crucial for the establishment of oral tolerance and for the induction of food immune reactivities [48]. Food immune reactivities can result from many environmental factors that can disturb the homeostasis of the immune system, resulting in the penetration of dietary proteins and non-tolerogenic peptides to the submucosa. To avoid immune reactivity to food antigens, the body employs the inflammatory immune defenses, including secretory IgA (SIgA) antibodies and hyporesponsiveness to innocuous agents, particularly dietary antigens and the commensal gut microbiota [49, 50]. The induction of these homeostatic mechanisms depends on exogenous stimuli, and the neonatal period is particularly critical to this end. Both the intestinal surface barrier with its reinforcement by SIgA and the immunoregulatory network require adaptation.

In most cases, this adaptation is remarkably successful in view of the fact that a ton of food, perhaps including 100 kg

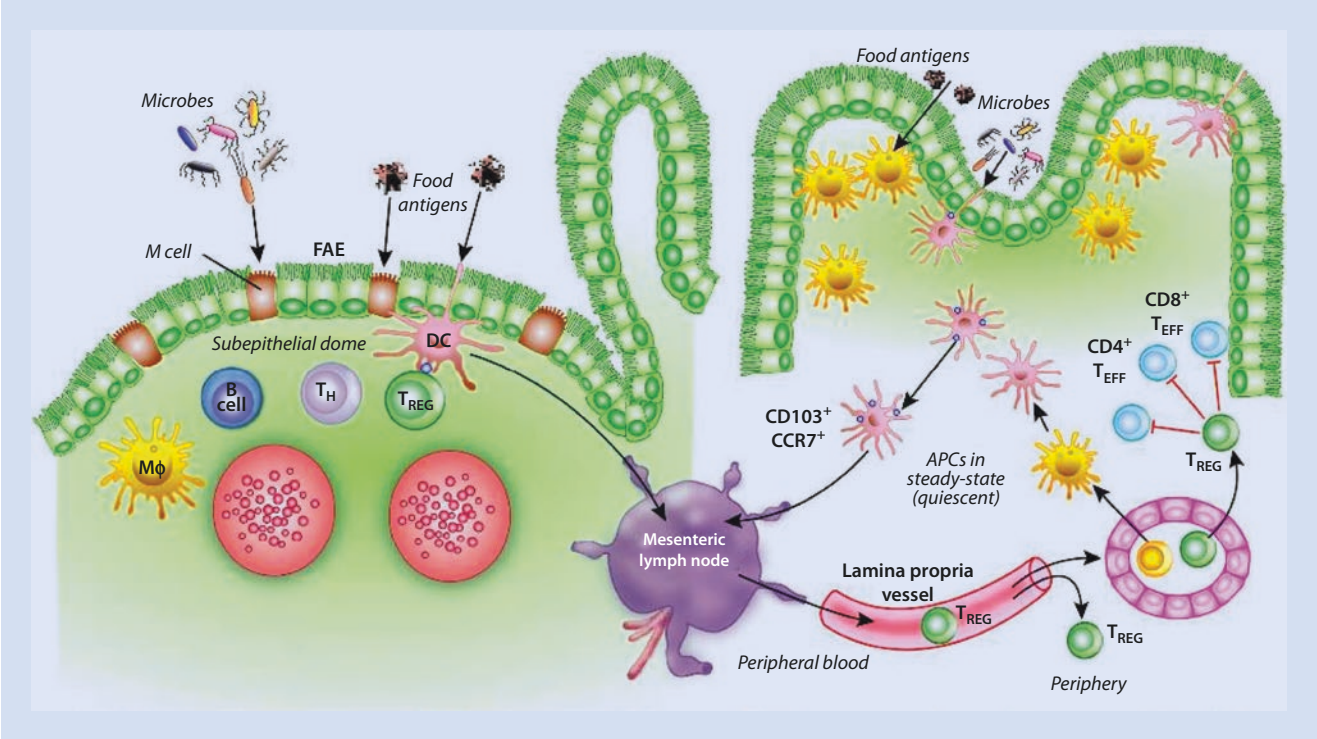

Fig. 19.18 The immunoregulatory network. Some antigen-presenting cells extend their dendrites between epithelial cells to sample luminal antigens. Such dendrites can also be seen in the follicle-associated epithelium (FAE) of gut-associated lymphoid tissue (GALT). Subepithelial APCs, mainly CD103 + CCR7+ dendritic cells (DCs) with captured antigen, migrate via draining lymph to mesenteric lymph nodes where they either mature to become active APCs that stimulate TEFF for productive immunity or become conditioned for tolerance via the generation and/or expansion of TREG cells. These inductile TREG cells migrate via efferent lymph to peripheral blood and then to the mucosa or the periphery where they exert anti-inflammatory control of CD4+ and CD8+ TEFF cells

of proteins, may pass through the gut of an adult human being every year without causing adverse reactions. Food immune reactivity reflects a lack of such homeostasis, either due to retarded immunological development with immaturity of the intestinal surface barrier or a persistently imbalanced immunoregulatory network. Both homeostatic deficiencies may be associated with immune reactivity, in particular IgA and IgG production against innocuous antigens, such as food proteins [51].

The mechanism of oral tolerance to food antigens and microbiota is shown in Fig. 19.18.

Understanding the mechanisms responsible for the induction of oral tolerance [52–54] is helpful in the design and introduction of vaccines for autoimmunities. For example, tolerance can be restored by sublingual immunotherapy [33, 55, 56], by a rush program of specific oral tolerance induction [57], and by introducing the triggering antigen nasally [58]. In a study on diabetes, intranasal administration of insulin, GAD-65, and even gliadin to 4-week-old, non-obese, diabetic (NOD) mice significantly reduced the diabetes incidence and lowered the insulitis. Likewise, another study [59] demonstrated that intranasal administration of glutamic acid decarboxylase 65 (GAD-65) could prevent murine, insulin-dependent diabetes in NOD mice.

It is interesting to note that gliadin has been shown to be cross-reactive to GAD-65 [60]. The information collected in this chapter shows that intranasal administration of either substance can be effective in reestablishing oral tolerance and either preventing or curing type 1 diabetes and other autoimmune diseases in which food antigens play a role.

19.5.2 Central Tolerance

Central tolerance refers to the tolerance established by certain events that occur in the early development stages of a lymphocyte. These events serve to focus these agents of the immune system onto pathogens (non-self) and away from innocent healthy tissue (self). This tolerance toward self is induced at the primary sites of lymphocyte development. For B cells, this is the bone marrow and lymphoid organs, while for T cells, it is the thymus [61, 62]. In these sites, maturing lymphocytes are exposed to self-antigens presented by medullary thymic epithelial cells and thymic dendritic cells, or bone marrow cells. Self-antigens are present due to endogenous expression, importation of antigen from peripheral sites via circulating blood, and –in the case of thymic stromal cells – expression of proteins of other non-thymic tissues by the action of the transcription factor named autoimmune regulator (AIRE). The lymphocytes will be unable to develop tolerance unless they encounter these antigens.

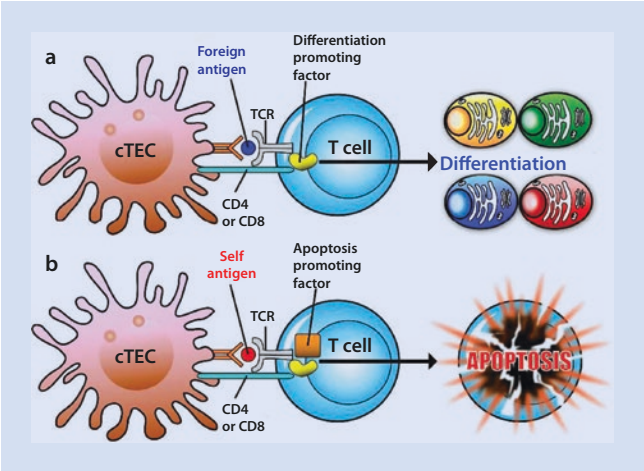

Fig. 19.19 How presentation of a foreign antigen or a self-antigen can lead to differentiation or cell death. **a** The cortical thymic epithelial cell (cTEC) presents a foreign peptide antigen to a T cell's TCR, sending signals that lead to differentiation. **b** Presenting a self-antigen peptide sends signals that lead to the T-cell lymphocyte's apoptosis or cell death

When a cortical thymic epithelial cell (cTEC) presents an antigen peptide, some lymphocytes have receptors that bind strongly to self-antigens, making them potentially strongly reactive to self-tissue. These autoreactive lymphocytes are removed before they develop into fully immunocompetent cells, for the most part by induction of apoptosis of the autoreactive cells (clonal deletion) and to a lesser extent by induction of anergy (a state of non-activity), or even receptor editing [61] (see Fig. 19.19).

The affinity of the peptide-MHC complex ligands also plays a role. If the peptide-MHC complex has low-affinity ligands, the T-cell receptor complex (TCR) will deliver signals that will promote the T cell's differentiation. However, if the peptide-MHC complex has high-affinity ligands, the TCR will deliver signals that promote the T cell's apoptosis (see Fig. 19.19).

The deletion threshold is much stricter for T cells than for B cells. This is because T cells alone can cause direct tissue damage, while B cells need costimulatory signals from T cells as well as a recognized antigen to proliferate and produce antibodies [63]. It is also more advantageous for the immune system to let its B cells recognize a wider variety of antigens so it can produce antibodies against a greater diversity of pathogens [64]. This process ensures that T and B cells that could initiate a potent immune response to the host's own tissues are eliminated while preserving the ability to recognize foreign antigens.

Weakly autoreactive B cells may also remain in a state of immunological ignorance, simply not responding to stimulation of their B-cell receptor. Alternatively, some weakly self-recognizing T cells are differentiated into natural regulatory T cells (*nTreg* cells), which act as sentinels in the periphery to calm down potential instances of T-cell autoreactivity.

19.5.3 Peripheral Tolerance

Peripheral tolerance describes the mechanisms that take place outside of primary lymphoid tissues to prevent lymphocytes from initiating potentially dangerous immune responses against the body's own tissues or against other harmless materials, such as food or commensal organisms. It takes place in the immune periphery after the T and B cells migrate from the primary lymphoid organs. Its main purpose is to ensure that self-reactive T and B cells that escaped the purging of central tolerance do not cause autoimmune disease [61, 65].

Peripheral tolerance is established by different but somewhat overlapping mechanisms that mostly involve T cells, in particular $CD4^+$ helper T cells, which coordinate immune responses and give B cells the confirmatory signals they need in order to produce antibodies, as already mentioned above [33, 59]. T cells that have left the thymus are relatively but not completely safe; unwarranted immune response toward normal self-antigens that were not eliminated in central tolerance can still occur. Some of the mature T cells may have receptors (TCRs) sensitive to self-antigens present in such high concentration outside the thymus that they can bind to "weak" receptors. Alternatively, the T cell could react to a self-antigen it had not previously encountered in the thymus (tissue-specific molecules such as those from the islets of Langerhans, brain, or spinal cord not expressed by the AIRE transcription factor in the thymic tissues).

These self-reactive T cells that escaped clonal deletion in the thymus can inflict cell injury to self-tissues unless they are eliminated or effectively neutralized in the peripheral tissue, chiefly by the previously mentioned nTreg cells [64, 65].

Appropriate reactivity toward certain antigens can also be quieted by induction of tolerance after repeated exposure, or exposure in a certain context. In these cases, there is a differentiation of naïve CD4+ helper T cells into induced Treg cells (*iTreg* cells) in the peripheral tissue or nearby lymphoid tissue (lymph nodes, mucosal-associated lymphoid tissue, etc.). This differentiation is mediated by IL-2 produced upon T-cell activation and TGF-β from any of a variety of sources, including tolerizing dendritic cells (DCs), other antigen-presenting cells, or in certain conditions, surrounding tissue [66].

Adaptive Foxp3 + CD4+ regulatory T cells, otherwise known as induced or iTreg cells, develop outside the thymus under subimmunogenic antigen presentation, during chronic inflammation, and during normal homeostasis of the gut. They are essential in mucosal immune tolerance and in the control of severe chronic allergic inflammation [66].

The Foxp3+ iTreg cell repertoire is drawn from naive conventional CD4+ T cells, whereas natural Treg (nTreg) cells are selected by high-avidity interactions in the thymus [67].

There are other regulatory immune cells aside from Treg cells that mediate peripheral tolerance. These include T-cell

subsets similar to but phenotypically distinct from Treg cells, such as TR1 cells that make IL-10 but do not express Foxp3, TGF-β-secreting TH3 cells, and other less well-characterized cells that help establish a local tolerogenic environment [68]. B cells also express CD22, a nonspecific inhibitor receptor that dampens B-cell receptor activation, and a subset of B regulatory cells makes IL-10 and TGF-β [69]. Some DCs can make indoleamine 2,3-dioxygenase (IDO), which depletes the amino acid tryptophan needed by T cells to proliferate, thereby reducing immune responsiveness. Additionally, DCs have the capacity to directly induce anergy in T cells that recognize antigens expressed at high levels and thus presented at steady state by DCs [70, 71].

19.6 Dietary Intervention

It is basic knowledge that eating bad food, the wrong food, can make us sick. Nowadays we can elaborate about sensitivities and immune reactivities and autoimmunities, but the easiest way to put it is: Bad food makes you sick. The converse is equally easy to understand; good foods, or the right foods, make you healthy. To elaborate on this in turn, the right foods can not only keep you healthy but can actually help to reestablish tolerance and fix or repair deficiencies or dysfunctions in your health and immune system.

Vitamins are pretty much taken for granted. Everyone knows they're generally good for you, but so what? People who consider themselves healthy don't think twice about not taking any vitamins at all. However, accumulated evidence shows that a healthy diet containing phytochemicals, fatty acids, and vitamins such as A, C, and D have a direct effect on the maintenance of our long-term health [72].

We have previously discussed innate lymphoid cells (ILCs). They are essential for orchestrating immune responses and discriminating between friendly bacteria, harmless food particles, and harmful food antigens. The binding of these cells to vitamins and their metabolites contributes significantly to immune homeostasis [73, 74].

Vitamin A or retinoic acid (RA) is an important requisite in the conversion of naïve $CD4^+$ cells into iTregs [75]. Metabolites of vitamin A, in particular all-trans RA, are an important determinant in mucosal immune homeostasis and the maintenance of oral tolerance. RA is key in the maintenance of mucosal immune homeostasis mediated by TGF-β1 and the IL-10 expression of T cells, which prevents immune reaction to normal food antigens and the development of gut inflammatory disorders [76].

Vitamin B comprises eight different members involved in various biochemical pathways in cell metabolism. Vitamin B6 influences cell growth and differentiation by enhancing the metabolism of amino acids, nucleic acids, and lipids. Vitamin B6 deficiency can lead to impairment of immune function, and, conversely, its supplementation can repair and even enhance weakened immune response. Vitamin B9, also known as folic acid, is essential for protein and nucleic acid synthesis. Low levels of this vitamin can alter the activity of NK cells and $CD8^+$ T cells. Vitamin B9 is essential for the activation of Bcl-2, the anti-apoptotic molecule that acts as a brake in cell survival; in the absence of vitamin B9, naïve T cells can differentiate into Treg cells but are unable to survive for a long period of time [77].

Vitamin C, or ascorbic acid, has been shown to be important in immunoregulation. Vitamin C deficiency can disrupt T- and B-cell function and NK cytotoxic activity [78–80]. A decrease in vitamin C may result in immune suppression [81]. Studies indicate therapeutic possibilities with vitamin C for the enhancement of NK-cell, T-cell, and B-cell function, as well as for immunoregulation and the induction of tolerance to autoantigens.

Vitamin D or 1,25-$(OH)_2D_3$ promotes the generation of tolerogenic or semi-mature DCs with a reduced ability to process and present the antigens of food and friendly bacteria to T cells. Vitamin D3 also promotes a general suppression of immune response and protects against various autoimmune disorders while enhancing the antimicrobial properties of monocytes and macrophages and increasing the body's defense against invading microorganisms. It also enhances the production of Toll-like receptors (TLRs) and triggering receptors expressed on myeloid cells (TREMs). Vitamin D has the potential to restore antigen-specific immune tolerance by inhibiting the maturation of dendritic cells or locking the cells in a semi-mature state so as to deprive them of their capacity to activate autoreactive T cells. Treatment with vitamin D is a promising tool for restoring the balance between immunogenicity and tolerogenicity in many autoimmune diseases [82, 83].

Aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor that is a crucial regulator in maintaining the number of intraepithelial lymphocyte (IEL) cells in the intestine. AhR is found in cells that are important in the defense against intestinal and extracellular pathogens and also helps in gene transcription and maintaining homeostasis in the immune system. It stands to reason that any food that helps AhR do its job is a food that's good to eat. Cruciferous vegetables such as broccoli, cabbage, cauliflower, kale, Brussels sprouts, and watercress, which contain *indole-3-carbinol*, are a major source of AhR ligands [84]. Plant-derived nutrients like indole-3-carbinol can work with AhR to shape the intestinal immune defenses and have an impact on the control of microbiota and overall immunity and health. However, if you're feeling dismay that your parents were right after all (they were) and you should be eating vegetables (you should), here's a bit of uplifting news.

Tryptophan is an essential amino acid that plays an important role in immune function. Yes, that tryptophan, the stuff in turkey that people blame when they feel sleepy after gorging themselves on Thanksgiving. Tryptophan in fact is found not just in turkey but in many plant and animal proteins, including chicken, beef, pork, fish, cheese, seeds, nuts, and beans [85, 86]. It is able to influence the immune system when it is converted into metabolites by the enzyme indoleamine 2,3-dioxygenase (IDO). This enzyme converts dietary

tryptophan to kynurenine, hydroxykynurenine, and xanthurenic acid; these metabolites can regulate immune function, inducing Treg cells to produce IL-10, thereby preventing asthma and allergy.

Tryptophan metabolites and naturally occurring compounds found in fruits and vegetables, such as resveratrol in grapes and quercetin in apples, can act on the AhR on intraepithelial lymphocytes, innate lymphoid cells, Treg cells, and Th17 cells, thereby controlling their functions.

Probiotics are defined by the World Health Organization as live bacterial species that confer a health benefit when administered in adequate amounts [87]. These are commensal bacteria among the gut microbiome's bacterial population that have been identified to provide their hosts with many health benefits, including intestinal homeostasis, and blocking the harmful effects of other microbiota. They directly compete with pathogens for various nutrients, stimulate innate and adaptive immune responses, and promote tolerance.

Good bacteria can convert fiber-containing molecules such as starch pectins, fructan, and cellulose into three major fatty acid metabolites: acetate, butyrate, and propionate. These metabolites or short-chain fatty acids (SCFAs) act as ligands for the GP43 receptor (GP43R) on Treg cells. They activate the Treg cells into expanding and producing a significant amount of IL-10 and TGF-β, which do not only enhance the oral tolerance mechanisms but can also control inflammatory immune responses in the gut. Dietary intervention with probiotics could be used for the prevention and alleviation of food immune reactivity, intestinal barrier dysfunction, and even autoimmunities (see Fig. 19.20) [88].

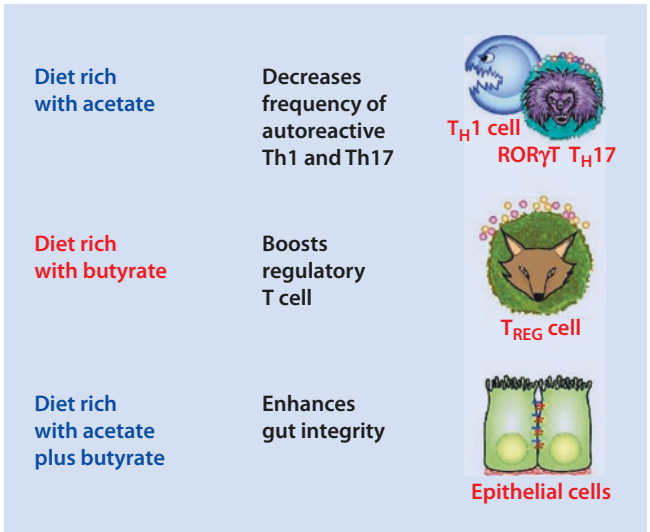

Fig. 19.20 How dietary intervention can help the immune system. Eating the proper foods with the right chemicals/ligands/metabolites can help maintain or repair the immune system in various ways. Only a few of these are named in the figure

19.7 Conclusion

The three major protective layers of the immune system (mucosal, innate, and adaptive) work together to protect an individual from the assault of environmental triggers such as infections, toxic chemicals, and immune-reactive foods. The mechanisms of the immune system comprise highly complex processes and myriad cells with a variety of functions, making it all too easy for an environmental trigger to cause a misstep or hiccup in the system.

As knowledge grows, the information gained is eventually put to use. The information we have presented here is gradually being applied in clinical practice. Such therapeutic interventions focused on the cells, molecules, and mechanisms of the immune system can have far-reaching benefits for a patient's immune system and health.

We now know that things as basic to life as foods are not to be taken for granted and that they can either help or hinder our immune system and, therefore, our health.

Understanding how the immune system works and how the mechanisms and components of the mucosal, innate, and adaptive immune systems all work together can help us to design modalities for the maintenance of immune homeostasis and the prevention of many immune disorders, including autoimmunities [89].

Acknowledgments We would like to acknowledge Joel Bautista for the preparation of this manuscript for publication and for the execution of the figures.

Learning Objectives

- Impact of infection on health and disease
- Malnutrition, inflammation, and the infectious processes
- Chronic diseases, nutrition, microbiome, and infection

20.1 Introduction

The complex nutrition-immunity-microbiome-infection-genomic connection is presented in this chapter, bringing their relationship together in an integrated view with a focus on the role of nutrients in maintaining the integrity of the immune system. Infection has been a primary challenge to human health and disease throughout history. It is now recognized that an individual's vulnerability to infection is associated with nutritional status. Malnutrition increases the risk of infection and immune system compromise. The past century's renaissance of nutrition science has supplied the increasing evidence for the roles that essential nutrients, dietary intake, environmental exposures, and nutrigenomic influences play in the ability of the immune system to respond and resolve infectious insults. The recognition of the importance of nutrition within the scope of assessment and intervention, which is often overlooked in healthcare, is presented as having an overall impact on outcome. The current knowledge of the role of nutrients and their interrelationships with the immune system and chronic disease provides scientific support for the nutritionally trained practitioner. This chapter will describe some of the key mechanisms and nutrient influences on the immune response as well as dietary and lifestyle considerations for treatment.

Nutritional deficiencies and insufficiencies have known associations with increased susceptibility to infectious disease. Infection can also increase requirement for nutrients and produce further undernutrition, infection, and compromise of the immune system, setting up a vicious cycle between malnutrition and infection [1, 2]. Malnutrition is the primary global cause of immunodeficiency for all age groups, especially for infant mortality with poor nutrition promoting underweight, weak, and vulnerable children. Optimum nutrition status allows the metabolic function defense and repair mechanisms to increase immune integrity.

Optimal nutritional status contributes to health maintenance and the prevention of infection. The function of healthy cells is maintained by adequate nutrition, movement, and sleep routines. Primary and secondary malnutrition may occur when each individual lacks the available clean food, nutrients, and water that are required. The healthy immune system enables the body's ability to adapt, recover, and survive. When there is disruption in the nutrient intake, the malnutrition that ensues contributes to a cascade of adverse metabolic events leading to illness. The nutritionally trained practitioner assesses an individual to identify where malnutrition may be present and develops an intervention with early delivery of essential nutrients in an effective and comprehensive manner. Healthcare practitioners are often challenged to understand the importance of adequate nutritional support in the prevention and treatment of infection, multiple organ failure, and most life-threatening systemic sepsis [3].

The aim of this chapter is to provide the current science for and a description of the interaction between nutritional status of an individual and immunological susceptibility to infection, as well as integrative and functional approaches to interventions that may be considered to restore immune integrity and restore wellness. There will not be an in-depth review of immune function. Please refer to the excellent presentations of the immune system by Dr. Vodjani in ▶ Chaps. 19 and 49.

This chapter is divided into three sections.

1. Impact of infection on health and disease
2. Malnutrition, inflammation, and the infectious processes
3. Chronic diseases, nutrition, microbiome, and infection

20.2 Impact of Infection on Health and Disease

Until the beginning of the nineteenth century and the industrial revolution, illness was primarily impacted by physical injury and acute infections related to poor sanitation practices that allowed a higher prevalence of infection. Throughout thousands of years of history, the human body has survived through the strength of several defense mechanisms, including an alert immune system, the impermeable skin membrane, and gut barrier, and the more recently recognized microbiome that shields all body orifices. It has been well established, even by Hippocrates almost 3000 years ago, that these mechanisms are dependent on an optimal nutritional status in order to maintain health and to prevent infection.

> Illnesses do not come upon us out of the blue. They are developed from small daily sins against Nature. When enough sins have accumulated, illnesses will suddenly appear. –Hippocrates (c. 460 – c. 370 BC)

During the nineteenth century, outstanding scientific discoveries occurred and changes in philosophy took place regarding the biological functions within the human body, enabling greater appreciation of the fact that when the biochemical mechanisms of our defense system are disrupted, it increases vulnerability to infectious disease.

20.3 Key Metabolic Mechanisms for Defense and Repair

- Enterohepatic circulation (see ▶ Chap. 16)
- Phase I and phase II biotransformation/detoxification (see ▶ Chap. 14)
- Gastrointestinal, lung and skin/barrier integrity/membrane integrity (see ▶ Chap. 12)
- Mitochondrial function
- Methylation (see ▶ Chap. 18)
- Hormonal function (see ▶ Chap. 32)
- Autophagy (see ▶ Chap. 51.2.6)
- Happiness (see ▶ Chaps. 6 and 30)

20.4 Insults to Our Defense and Repair Systems

20.4.1 Increased Toxin Load

As the industrial revolution evolved, increased toxin exposure accumulated from the discovery and use of petroleum which released petrochemicals and mercury into the air, the discovery of mercury (e.g., used in making the British top hat), the common use in dentistry of mercury (comprising about 50% of dental amalgam material), and pollution from industrial practices into rivers and the resulting contaminated water supply. The trend for increased environmental toxin exposure has continued to grow, so that at the time of this publication there have been more than 80,000 chemicals created with relatively few tested for safety. A most pervasive and hazardous pesticide toxin, glyphosate, is now used nearly universally in agriculture, thereby ending up in our water and food supplies.

20.5 Antimicrobial Resistance (AMR)

There has been continuous improvement in sanitation practices, perhaps too robustly going beyond the abilities of human and animal life to balance with the microbial world to avoid development of "superbugs" that have become resistance to antibiotics. The challenge of acute infections is of great concern to public health because of antimicrobial resistance (AMR) and the rise of "superbugs" that are considered the biggest threats to modern healthcare [4]. The primary driver of AMR is thought to be the overuse of antibiotics in humans and agricultural animals and overuse of antibacterial hand soaps and gels.

20.6 Gastrointestinal Dysbiosis: From Mouth to Anus

The two largest defense barriers to infection are the skin and the gastrointestinal tract (gut). The mouth and oral cavity provide the beginning of defense and repair by mastication, saliva digestives, and endocrine immune glands (parotid, tonsils, adenoids) preparing food that enters the gut for digestion and absorption. The next step is the pH 1–3 acid bath the bolus of food passes through in the stomach with antimicrobial action suppressing any pathogens traveling in with your food. The small intestine is the next pass, bathing the bolus in bile, pancreatic digestive enzymes, and bicarbonate, ready for the serious work of digestion. This is the location where the gut houses more than 70% of our body's immune tissue (lymphoid tissues) and, when compromised by insults, we become more vulnerable to infection weakening our immune integrity. Those lymphoid immune cells also depend on a healthy microbiota's symbiotic relationship to optimally function. The gut is frequently referred to as "the second brain" [5] because of its generous secretion of neurotransmitters and direct connections to and from the brain, the enteric nervous system. When insults like antibiotics, emotional upsets, stress, infection, chemicals, or toxic metals enter the gut, the gut barrier breaks down and suffers intestinal permeability ("leaky gut") that allows for non-desirable molecules to be absorbed and enter the blood and lymphatic systems, triggering an immune response of loss of self-tolerance, or an antigenic response against one's own tissue [6]. Once someone experiences a "leaky gut," a pro-inflammatory cascade initiates, adding a burden to the immune system and increasing vulnerability to infection.

20.7 Stressors

Stress can insult our defense and repair in several forms: biological, emotional, and energetic stressors. As stressors increase, there is a resulting biological stress, along with a concurrent increase in nutritional requirements. If the food intake cannot keep up with meeting the nutritional needs under stress, malnutrition ensues. Unfortunately, with the increased consumption of the standard American diet (S.A.D.), the population eats more calorie-dense, nutrient-depleted, processed, and high-sugar foods. A majority of the US population does not have the available nutrients to meet the essentials of a generally more stressed society [7]. One of the most prevalent nutrient deficiencies and insufficiencies in the USA from NHANES studies are "40% deficient in Vitamin A, C, D & E, calcium or magnesium deficient and >90% do not get enough choline, fiber & potassium." [6] (◘ Fig. 20.1).

About 65% of the population does not even meet the recommended daily allowance (RDA) for magnesium [8, 9]. More than two-thirds of the US population are either overweight or obese. This population subgroup has a higher risk of several chronic diseases.

Early in the twentieth century, great trust and hope were generated by Alexander Fleming's discovery of penicillin and the world of antibiotics [10], with the anticipation of ending uncontrolled bacterial infection. Now in the twenty-first century, as science looks back on the use of antibiotics, recognition is increasing that the overuse of antibiotics is enabling the development of what are now termed "superbugs."

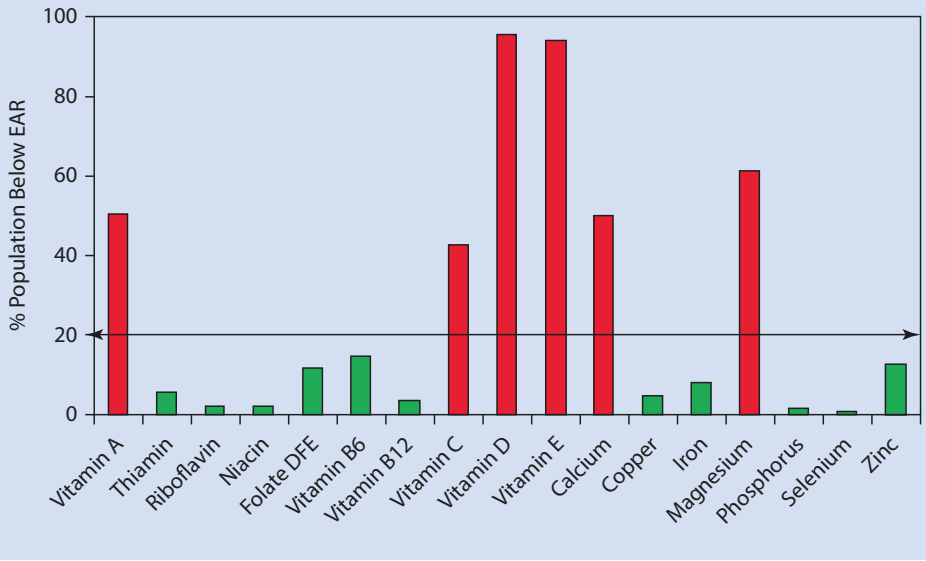

Fig. 20.1 NHANES 2001–2008 micronutrient deficits. Percentage of the adult population (aged 19 years) with vitamin and mineral intakes below the EAR for individuals (data from NHANES 2001–2008). Usual intakes from foods were estimated by using the National Cancer Institute (NCI) method [8]. (Reprinted from Agarwal et al. [8]. With permission from Taylor & Francis)

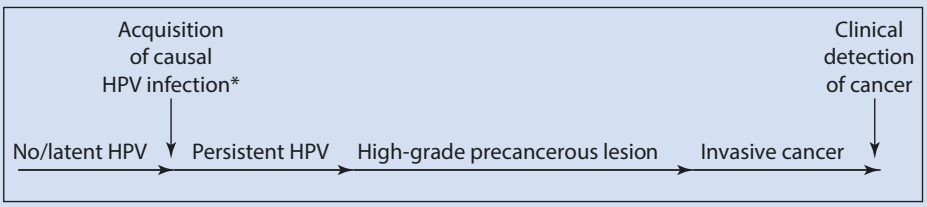

Acquisition of causal HPV infection*
Clinical detection of cancer

Persistent HPV
High-grade precancerous lesion
Invasive cancer
*Age (years) for all high-risk HPV genotypes, stratified by HPV-16, and other non-HPV-16 genotypes

Fig. 20.2 HPV lifespan spectrum [12]. (Reprinted from Burger et al. [12]. With permission from Oxford University Press)

Superbugs are beginning to threaten the success of medicine and pharmacology. The antibiotics have weakened the defense mechanisms of the microbiome shield that humans have depended on throughout history. Public health concerns are increasing that the overuse of antibiotics in humans and animal husbandry, along with antimicrobial antiseptics, has become a health threat through the weakening of the microbiome protection of the population.

The discovery of subclinical unresolving infections that are associated with many of the chronic diseases is beginning to be appreciated by the global medical community. Infection increases infection-related morbidity and mortality [11]. Subclinical-level long-latency infections often go unnoticed while they alter and sometimes mutate tissue cells over time, leading to an acute disease. Examples of infection connections to chronic disease are:

- HPV virus causal of cervical cancer and neck/head cancers [12] (Fig. 20.2)
- *H. pylori* increased risk of gastric cancer [13] (Fig. 20.3)
- HSV-1 increasing risk of Alzheimer's disease [14]
- *Klebsiella pneumoniae* association with rheumatoid arthritis [15, 16]
- EBV and CMV combo-viral increasing risk of various cancers [17]
- *Chlamydia pneumonia* and atherosclerotic plaque formation [18]

With nutritional status being a major factor affecting host resistance to infection, this chapter focuses on how to assess a chronic disease sufferer's "infection load" or "infection status" using an integrative and functional lens, searching for the disease etiology and impaired resolution of inflammation (resolution biology) [19]. This assessment of infection status should become part of the nutritional and metabolic assessment differential. It rules out, or identifies, if infection is part of the etiology and pathophysiology of a disease condition. Once identified, targeted intervention proceeds to improve successful outcomes of restoring wellness (Fig. 20.4).

20.8 Malnutrition, Inflammation, and the Infectious Processes

Infection, as well as trauma or excessive visceral fat, appropriately perturbs the immune system into secretion of inflammatory molecules like cytokines, acute phase reactants, and others [11]. It is not possible to cover the scope of the physiology of the immune system and inflammation in this space; the focus of this chapter is to describe how malnutrition and insufficiencies of specific nutrient groups can perpetuate compromising the immune system and the microenvironment, so the natural immune mechanisms of defense and repair from infection are weakened (see ▶ Chaps.

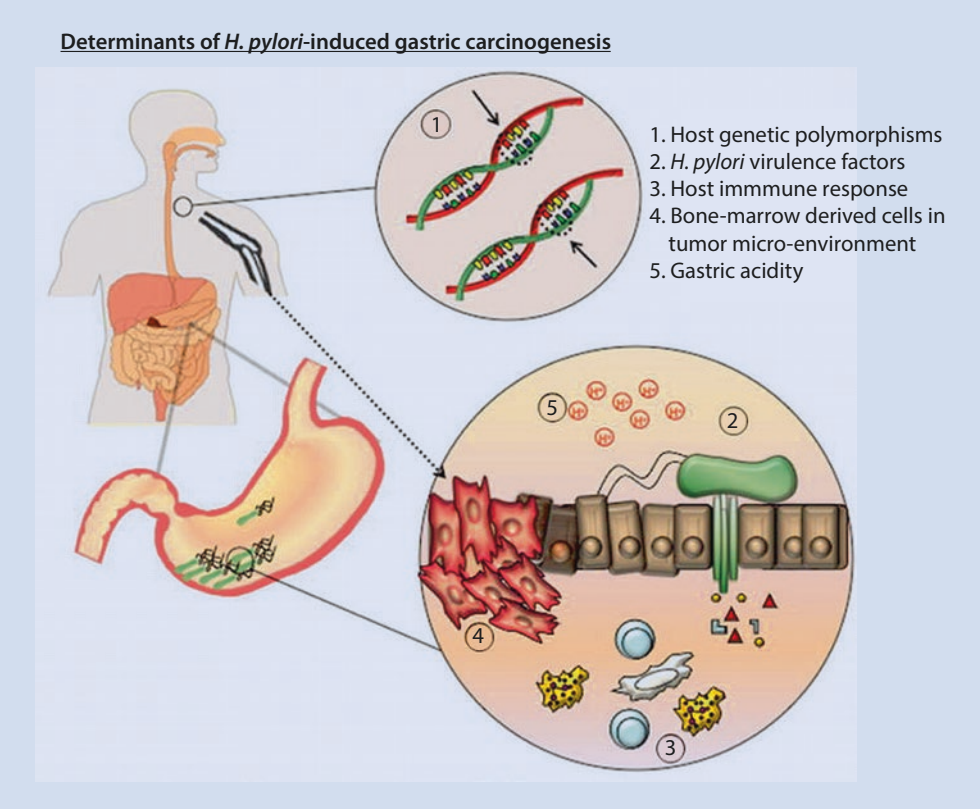

Fig. 20.3 *H. pylori* increased risk of gastric cancer [13]. (Reprinted from Kim et al. [13]. With permission from Elsevier)

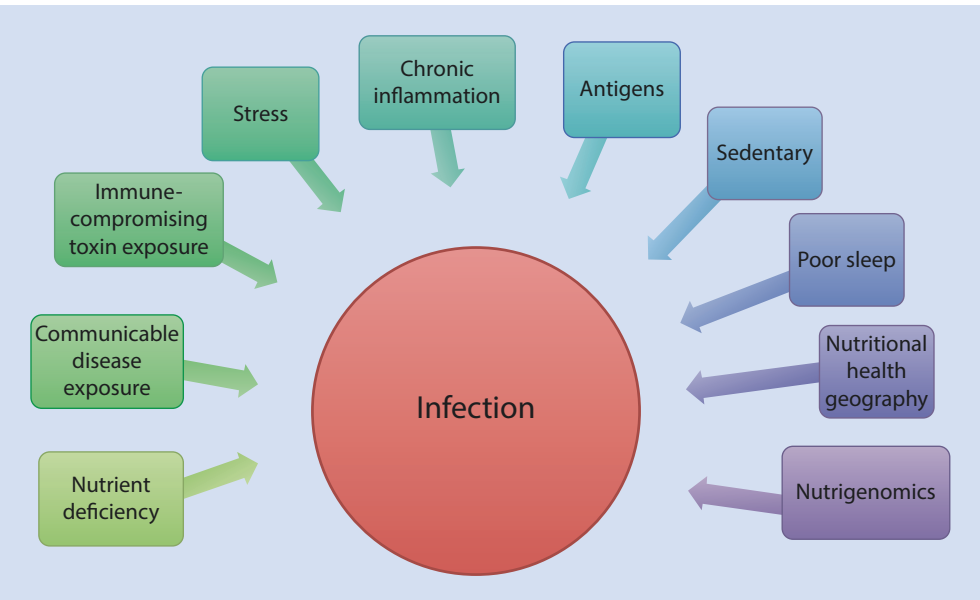

Fig. 20.4 Key nutritional, lifestyle, and environmental influences on infection

19 and 50). Inflammation almost always accompanies infection and, when prolonged, sets up susceptibility for all chronic diseases.

For acute infections, this inflammatory response is a critical part of tissue healing, with increased blood flow and heat. Increased heat can involve local tissue or produce systemic natural hyperthermia with fever. If infection continues to be unresolved, it can produce a prolonged state of inflammation with continuing subclinical infection(s) that over time can result in a loss of self-tolerance and perturb metabolic mechanisms toward diseased tissue that can lead to any of the chronic diseases. The inflammatory load of an individual should be assessed for each chronic disease and infection ruled out as a potential contributor to total body inflammation [20].

Tuberculosis (TB) is a leading cause of death worldwide, despite being preventable and often curable [21, 22]. It is prevalent in malnourished populations with poor sanitation [20].

Schwenk states that TB, also called "consumption," is predisposed by a state of macro- and micronutrient deficiencies.

There is a complex relationship between tuberculosis and malnutrition, in that TB can increase nutrient requirements and lead to a worsening of nutritional status. In high-TB rate countries, vitamin A, carotenoids, and vitamin D levels are found to be low and deficient. Nutritional correction of malnutrition factors is considered part of the best approach to the treatment of tuberculosis [20, 21].

20.9 Diagnosis of Nutrition Status and Infection-Related Diseases

There is much evidence for association or causal nutritional insufficiencies or deficiencies increasing the risk of someone becoming infected. Once infected, levels of tissue inflammation increase until clinically observable (see ◘ Fig. 20.2) and may linger long term unless resolved back to wellness. If the infection continues even at a subclinical level, it can continue to weaken the host integrity of the immune system [11].

Inflammation is the body's normal response and protects the body from infection from pathogens like bacteria or viruses, as well as injury. Inflammation can be acute, which should be short-lived as the body resolves an infection or injury, or chronic and long term and can be destructive, leading to chronic diseases. Examples of chronic diseases that can develop from a long-latency infection are periodontitis, asthma, inflammatory arthritis, and inflammatory bowel disease.

Conventional therapies for chronic inflammation use anti-inflammatories primarily from two categories of pharmaceuticals: steroids and nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs counteract enzymes and prostaglandins. NSAID use of more than 10 days is not desirable, due to increased risk of stomach ulcers and gastrointestinal bleeding and sometimes adverse effects like worsening of asthma or kidney problems.

Cardinal signs and physiology of inflammation

Rubor (redness): increased blood flow
Tumor (swelling): exudation of fluid
Calor (heat): exudation of fluid, increased blood flow, release of inflammatory mediators
Dolor (pain): chemical mediators; inflammatory exudates stretching pain receptors and nerves
Functio laesa (loss of function): pain, fibroplasia, metaplasia, disruption of structure

For the IFMNT practitioner, changing the patient's dietary intake and use of dietary or herbal supplements to correct nutrient deficits or excesses can support the underlying systems promoting the inflammation. For instance, NSAIDs act on suppressing eicosanoid and prostaglandin metabolites. Assessment of blood RBC fatty acids (linoleic (LA) and alpha-linolenic acid (ALA) and their metabolites, gamma-linolenic acid (GLA), di-homo-gamma-linolenic (DGLA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) reveals where there may be an underlying imbalance directly related to what they eat. Developing a diet plan to *rid* intake of inflammatory foods and *get* foods that are anti-inflammatory is a desirable goal. (see ▶ Chap. 43). Key foods include therapeutic use of food oils that can modulate a person's fatty acid status and provide ability to control inflammation. Phytonutrients rich in the variety of colorful fruits and vegetables have powerful anti-inflammatory action. Some herbs have excellent evidence of anti-inflammatory support with successful practice-based experience.

Anti-inflammatory foods, herbs, and dietary supplements targeted recommendations based on patient assessment

Foods

Whole-foods, pesticide-free, vegetable, and fruit variety of color, adequate protein, healthy fats and oils, foods-rich in herbal components, and hydration; minimize or avoid processed and high-sugar foods and beverages; avoidance of identified antigenic foods. (see ▶ Chap. 43)

Herbs

- Turmeric/curcumin
- Resveratrol
- Boswellia
- Artemisinin
- Garlic
- Quercetin (suppresses mast cells)
- Proteolytic enzymes: bromelain, papain, trypsin, etc. (contraindicated for alpha-1-antitrypsin deficiency+ genetics)

Dietary supplements

- Vitamin C (contraindicated for hemochromatosis+ genetics)
- Adequate methyl nutrients
- Vitamin D3 (if indicated per personalized assessment)
- Vitamin A (if indicated per personalized assessment)

Infectious processes are biological stressors that alter the requirement of an individual metabolism beyond the RDA/RDI recommendations. Recognition of this principle drove the emergence of the field of orthomolecular nutritional therapy early in the twentieth century, leading to provision of the right nutrients at a molecular and cellular level. Under high-stress conditions, micronutrient requirements are altered [23]. For example, vitamin C requirements as a primary cellular antioxidant vary for an individual depending on the stress load, diet, gastrointestinal function, and genomics [24] as stated by Dr. Tim Spector, "there is a lot of variability in the ways in which healthy people react to food (and nutrients)" [25]. With the recognition of how unique and diverse individual physiologic immune responses are to food and lifestyle, the inclusion of a per-

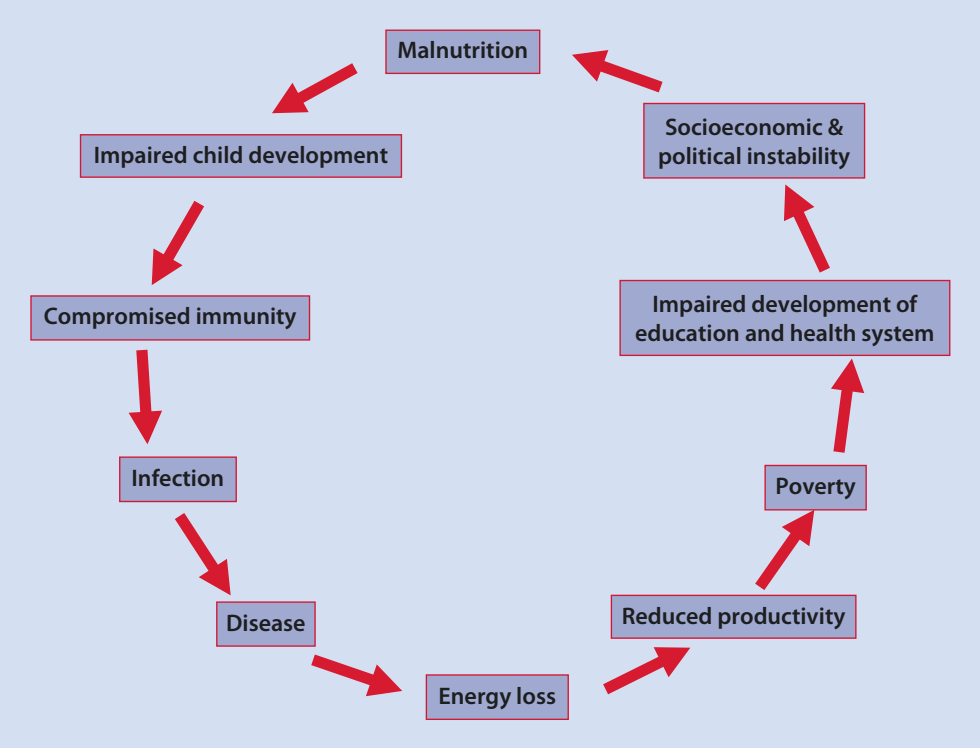

Fig. 20.5 Protein energy malnutrition increases prevalence of infection, leading to energy loss for the individual [2]. (Reprinted from Schaible and Kaufmann [2]. With permission from Creative Commons License)

son's nutrition status as part of their differential exam for development of a comprehensive treatment plan is of utmost importance.

Over human history, many cultures have evolved food traditions to meet specific health needs such as pregnancy, or infection, or child development. Records from Hippocrates describe specific foods to treat various disease conditions. In the Middle Ages, eggs were soaked in vinegar to dissolve the eggshell, rich in calcium and minerals, to be given to a pregnant woman. Various herbal teas were given for various types of infections and many other conditions. Besides food being a source of nutrients, herbal and nutraceutical oral supplementation became prevalent in the eighteenth century. In 1831, the first intravenous (IV) technology was attempted for treatment of cholera by a Scottish doctor, Dr. Thomas Latta. It took another 100 years for further development of intravenous therapies and only became commonly available clinically by licensed practitioners in the 1960s. Once determined safe and clinically feasible, it was embraced by many medical specialties where patients were impacted by compromised gastrointestinal function and malnutrition [26]. Today, many hospital and clinic infusion centers administer IV vitamins, mineral and nutrient cocktails, and intramuscular (IM) nutrients to support nutritional status of individuals seeking prevention, or as prescribed due to compromised oral dietary intake. IV treatments can provide nutrients for individuals with increased nutrient requirements, especially with the biological stressors presented by acute or chronic infections.

One of the most life-threatening infectious conditions is severe sepsis [27] with no effective treatment options. In 2014, the results of one of the first clinical trials for IV ascorbic acid at Division of Pulmonary Disease and Critical Care Medicine, Department of Internal Medicine, School of Medicine, Virginia Commonwealth University were published.

The conclusion of the $n = 26$ human trials with severe sepsis and a variety of diagnoses of cancer, respiratory failure, and others was that infusion of intravenous ascorbic acid was safe and may positively influence patients when challenged with severe sepsis with multi-organ failure. The study showed improved lower biomarkers of inflammation, C-reactive protein (CRP), and procalcitonin (PCT) that correlate with the overall extent of infection. Higher levels of both have been biomarkers linked to higher incidences of organ injury and death in the critically ill. These two biomarkers proved accurate to assess effectiveness of the IV ascorbic acid. Thrombomodulin (TM) was the biomarker used to measure endothelial injury status and showed similar improvement Fig. 20.5.

20.10 Differential for Nutritional Infection Risk

20.10.1 Look for Evidence of Infections

Toolbox to identify infectious relationship with nutrition status:

- Nutrition physical exam (see ▶ Chap. 40)
- Medical history: diagnosis, medical event history, infectious history, residential location

- Signs and symptoms: medical symptoms questionnaire (MSQ)
- Laboratory and procedural testing (basic nutrition-related and, if applicable, for disease-specific and sometimes patient-specific markers)
- Bioelectrical impedance analysis (if available)
- Laboratory nutrition status and infection-related biomarkers (Table 20.1 and Fig. 20.6).

The nutrients most studied regarding immunonutrition that should be considered in the assessment are listed in Table 20.2 and will be discussed below.

20.11 Chronic Diseases, Nutrition, Microbiome, and Infection

All chronic diseases have associations with acute or subclinical infections as potential etiologies for a chronic disease individual. Infections are caused by the exposure to such pathogens as virus, bacteria, parasites, fungi, or prion. Many chronic diseases have known nutrient-microbiome-infection interactions [57]. When completing an initial assessment differential consideration of an infectious component of any patient presenting with a chronic disease, it should be part of an initial assessment differential to identify if infection could be part of the pathophysiology.

Malnutrition, altered microbiome, and infection interact to influence health and disease in the developed and developing world. Infectious morbidity is significant in the malnourished, whether nutrient insufficiencies or overnutrition. Infections significantly compromise utilization of oral nutrition and the immune lymphoid tissue in the gastrointestinal tract disturbing the microbiome. Malnutrition predisposes a person to infection, and restoring the injured nutritional status improves immune integrity. Improving nutritional status reduces risk of infection, and when one does contract infection, there may be a reduction in the severity of systems.

Nutritional assessment currently makes use of many new technological modalities. The Integrative and Functional Medical Nutrition Therapy assessment model identification of "root cause(s)" of a condition starts by hearing the patient's story (see ▶ Chap. 39). When was the last time they felt well? Family history? Signs and symptoms? Diet history? Medications? Supplements? Toxin exposure? Other issues? The model explores the question of how a person's metabolism evolved to the current disease condition.

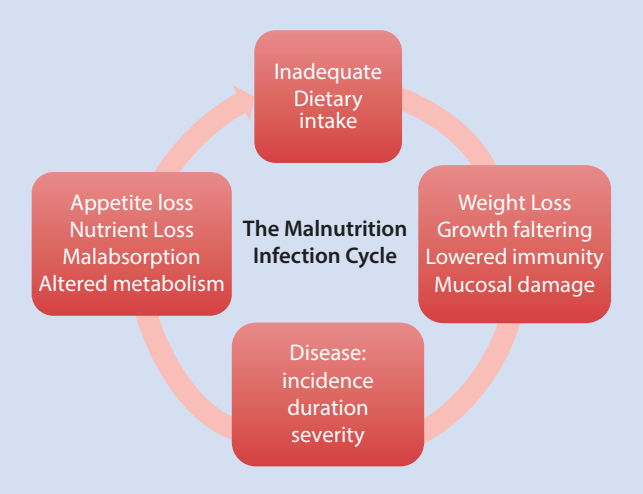

Fig. 20.6 The "vicious cycle" of malnutrition and infection. Spiral of malnutrition and infection [28]. (Adapted from Katona and Katona-Apte [28]. With permission from Oxford University Press)

Table 20.1 Immunonutrition assessment investigation tools

Test	Type	Practitioner options
Imaging	Diagnosis-related	Radiology
Functional testing	Digestive Hormonal Organic acids Structural	Functional medicine Endocrinology MD, DO, ND, LAc, RD, CNS, RN, NP, PA DC, DO, PT-classical
Mind-body	Psychology	MD, psychologist, family counselor therapist
Initial assessment and monitoring	Follow-up	Initial practitioner
	BIA	All; equipment required

20.11.1 Laboratory

With laboratory data to examine, a diagnostic profile begins to emerge to clarify the priorities of core physiological

Table 20.2 Key immuno-nutrient insufficiencies/deficiencies associated with or causal for subclinical or acute infections; key immune-nutrients foundational for healthy immune endogenous defense

Nutrient	Infection: deficiency connection	Reference	Symptoms	Testing to consider
Immune modulators				
Vitamin D	Immune modulator	[29–31]	Mood disorders; bone loss; joint pain; compromised immunity	Vitamin D25OH
Vitamin A retinol	Mucosal immunity	[22, 24]	Mucosal bacterial/ viral infections	Vitamin A, retinol; β-carotene
Phytonutrients polyphenols		[32, 33]		
Rate-limiting cofactors				
Folate	NK cell activity Cytotoxic cellular immunity Modulate T cell responses	[34]	Fatigue Infection Mood disorder	Folate, serum FIGLU
Zinc	Regulates intracellular signaling pathways in innate and adaptive immune cells	[34–36]	Skin conditions Poor smell Poor taste Frequent illness Nail spots	Zinc, serum Zinc, RBC
Magnesium	>300 enzymes cofactor Urine excretion under stress		One of the most deficient minerals in the USA Muscle tension Cramps	Magnesium, serum RBC magnesium
Iodine	Thyroid metabolism requirement	[37, 38] *UIC values* <20 μg/L (severe iodine deficiency) 20–49 μg/L (moderate iodine deficiency) 50–99 μg/L (mild iodine deficiency), 100–199 μg/L (adequate iodine intake) 200–299 μg/L (more than adequate iodine intake) >300 μg/L (excessive iodine intake)	Cysts Fibrocystic breasts Hypothyroid In utero developmental	Urinary iodine concentration (UIC) Iodine, random blood
Amino acids Arginine Lysine Glutamine	Nitric oxide (NO) Gut barrier support	Low grade evidence [39] Herpes Simplex [40]	Perturbed protein metabolism Poor healing Express herpes simplex skin rash Poor gut barrier repair	Plasma or urine amino acid profile
Antioxidants				
Vitamin C	Regulates cellular humoral immune function; increase macrophage Antihistamine requirements increase during infection Antiviral	[27]	Connective tissue impairment Skin conditions Poor wound healing	*Blood* Vitamin C CPT 82180

Table 20.2 (continued)

Nutrient	Infection: deficiency connection	Reference	Symptoms	Testing to consider
Vitamin E full-spectrum	4 tocopherols + 4 tocotrienols protective from oxidative stress/lipid peroxides	[29, 41]	Oxidative stress Premature wrinkles Cysts Leg cramps	Vitamin E (tocopherol) CPT 84446
Selenium	Thyroid peroxidase metabolism with vitamin E Selenoproteins special effects on cellular immunity Resistance to viral infections	[36, 41]	Hypothyroid Low glutathione blood levels Impaired detoxification	*Blood* Selenium, RBC Selenium CPT 84255
Gut secretions				
Short-chain fatty acids (SCFA)	Intestinal cells Anti-inflammatory Microbiome-gut- brain axis via immune system/vagal nerve Mucosal immunity	[42–47]	Inflammation Perturbed uric acid cycle Colon disease	Fecal collection
Bile acids	Fat emulsification duodenum Carrier of toxins/elimination	[48, 49]	Perturbed fat digestion Suppressed detoxification enterohepatic circulation	*Blood* Bile acids, total CPT 82239 or fecal collection
Anti-nutrients				
Endocrine disruptors	Circadian rhythm disruption that can modulate immune function	[50, 51]	Hormonal imbalance Insomnia Cancer	Blood or urine
Damaged food components/Western diet and food preparation Trans fat Oxidized fat Toxic metals Toxic chemicals "new-to-nature molecules" (cookware, pest control, pollutants, processed, etc.)	The damaged high-heat foods Chemicals Toxic metals ingested in foods and from food utensils during food preparation	[52]	Toxicity Symptoms vary	Blood or urine
Environmental toxins Mold/mycotoxins Natural gas carcinogenic Chemical vapors Pesticides	Neuropsychiatric immune disruption Vulnerable to infections increased risk for kidney failure, fertility problems, cancer, birth defects	[53–56]	Toxicities Chronic kidney failure Infertility Cancer Developmental Frequent infections	Specialty labs

imbalances for nutrition and lifestyle therapy. When focusing on assessing the existence of infectious activity, and the priority within the etiology of a disease condition, consideration of the three most likely physiological areas of immune imbalances are *defense and repair*, *assimilation, and structural integrity* (Fig. 20.7).

20.11.2 Assessment Laboratory and Clinical Tools

- Comprehensive Digestive Stool Analysis (CDSA) various labs provide CPT
- Ova and Parasitology (2–3 samples) CPT Code(s) 87177, 87209

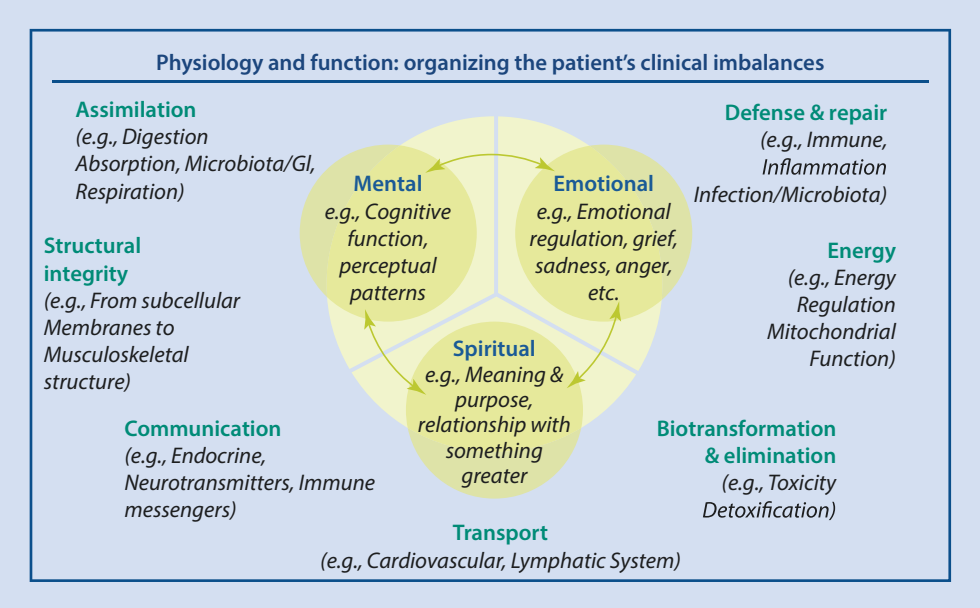

Fig. 20.7 IFM Matrix: physiology and function – organizing the patient's clinical imbalances [58]. (Used with permission from The Institute for Functional Medicine ©2015)

- Rule out other infections
- Calprotectin, fecal CPT 83993 [fecal calprotectin (FC]
- *Clostridium difficile* toxin/GDH with reflex to PCR (if diarrhea)
- Lactoferrin, fecal CPT 83631: leukocyte marker; intestinal inflammation
- Differentiate IBD from irritable bowel syndrome (IBS)
- Monitor patients with IBD for treatment response and relapse
- Diagnose inflammatory bowel disease (IBD)
- Occult blood, fecal

Defense and Repair Immune, Inflammation, and Infection/Microbiota Assessment Biomarkers

Blood

- Vitamin D 25-hydroxy
  Vitamin 25-OH serum levels have been associated with several comorbidities, such as infectious, autoimmune and neurological diseases, as well as neuromuscular disorders, which can lead to increased pain sensitivity [59–61]. Regarding the mechanisms of pain sensitization, vitamin D seems to stimulate anti-inflammatory processes in some cases and thus to relieve the painful sensation of many diseases [62–64].

- Vitamin A retinol [65]
  Vitamin A retinol is increasingly recognized in experimental and human studies to suppress inflammatory reactions and plays a significant role in normal mucosal immunity, regulation of T cell-dependent responses, antiviral activity [66], and cell trafficking.

  Adequate vitamin A status, whether from intake of preformed retinol or β-carotene, is important for preventing excessive or prolonged inflammatory reactions and infectious events [66].

- high sensitivity CRP (hs-CRP)
  High-sensitivity C-reactive protein (hs-CRP) is an acute-phase-reactant marker of systemic inflammation most often promoted by bacterial infection, central adiposity, neoplastic activity, or traumatic injury. The ideal level of hs-CRP is ≤0.6. hs-CRP elevation implies potential bacterial infection. The most common infections with elevated hs-CRP are periodontitis or necrosis of the jawbone. If an elevated CRP >1.0 and clinical oral exam and report of bleeding upon flossing or brushing, appropriate referral to a biological dentist for evaluation is warranted. If no dental/oral infection is identified, further investigation as to the root cause of the elevated hs-CRP is warranted. It is important to rule out a recent traumatic injury that may be related, and hs-CRP should be retested in a month or two to observe if injury affected the hs-CRP.
- CBC with differential
- Complete metabolic panel (CMP)
- Lipid panel
- Sed rate
- TSH
- **Bacterial/viral evaluation**
  - CMV IgG Ab CPT 86644–0.5 ml red top serum

Structural integrity Membrane structure affects the function of transport and communication at the cell membrane site and receptors; review if history of head/neck/dentition/back injury may affect brainstem and vagal nerve immune-related function; structure, dysfunction occurs. Dietary intake of these lipid groups is reflected in their endogenous structure and function [67].

- Cell membrane fluidity (BIA phase angle, fatty acid status)
- Structural: spinal alignment
- Dental: periodontitis – infection of the tissues that surround the teeth
- Cervical C1–C7 – brainstem and vagal assessment – check vagal tone [68]
- Thoracic T1–T5 – stenosis or injury, increased pain resulting in exaggerated immune inflammatory response
- Lumbar L1–L5 – stenosis or injury increased pain resulting in exaggerated immune inflammatory response

20.11.3 Key Nutrients Influencing the Risk of Infectious Disease (Fig. 20.8)

20.11.3.1 Vitamin D, A, E [69]

These fat-soluble vitamins have many metabolic roles, but for the focus on the immune system in this chapter, the role of immune modulation is discussed. The fat-soluble vitamins function synergistically; even the vitamin D and A receptors share the RXR nuclear receptor influencing each other. It is worth noting in nature that vitamins D2/3 and A are found in their food-rich sources together (e.g., liver, caviar/roe, egg yolk, etc.).

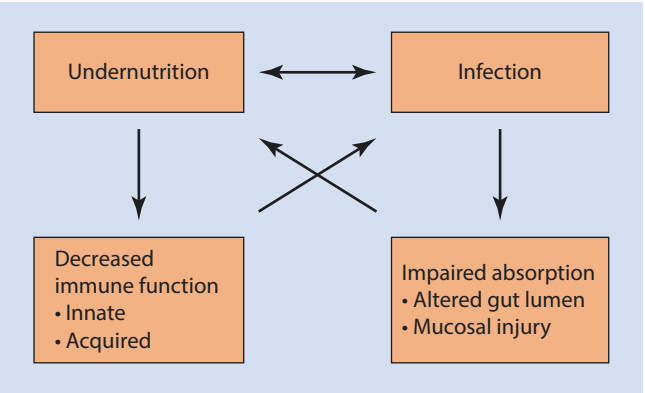

Fig. 20.8 Interactions between malnutrition and infection [28]. (Adapted from Katona and Katona-Apte [28]. With permission from Oxford University Press)

Lipids Phospholipids, oils, and fat foods – RBC fatty acid, lipid panel tests. The phospholipids, sterols, and eicosanoid fatty acids and their metabolites give structural and functional influences on cell signaling and prostaglandin "hormone-like" regulation to transport of components in and out of the cell compartments to nourish and regulate immune response of inflammation, hormonal modulation, and other undiscovered functions. When there is poor structure, poor function follows (see ▶ Chap. 10).

Methyl nutrients Vitamins B6, folate, B12, riboflavin, betaine, biotin, choline, SAMe, and amino acids methionine, cysteine, serine, and glycine [70, 71].

Methyl nutrients support the process of methylation with many roles within human metabolism, with DNA methylation being the underlying mechanism, and currently appear to be the primary messengers of epigenetic expression (see ▶ Chap. 18) identified in the etiology of developing cardiovascular, cancer, and neurological disease conditions. Methyl nutrients include vitamins (folate, riboflavin, vitamin B12, vitamin B6, choline) and amino acids (methionine, cysteine, serine, glycine).

Methylation involves biochemical pathways where the B vitamins and other cofactors like amino acids are rate-limiting cofactors.

20.12 Homocysteine Catabolism (Fig. 20.9)

20.12.1 Folate Metabolism

Folate is critical to many metabolic pathways like nucleic acid precursors, several amino acids, and erythropoiesis, the process in which new erythrocytes are produced. Elevated mean

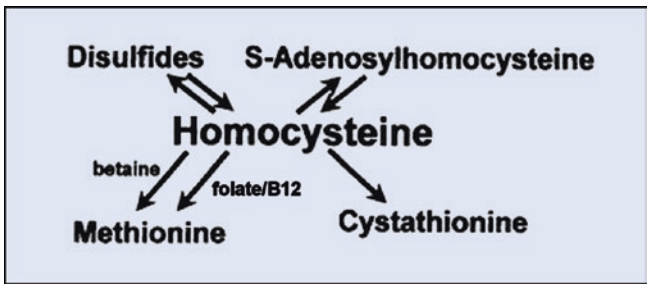

Fig. 20.9 Homocysteine major metabolic pathways in humans [72]. (Reprinted from Dudman et al. [72]. With permission from Oxford University Press)

corpuscular volume (MCV)on a complete blood count can suggest folate deficiency. Folate deficiency can be part of the etiology of enlarged RBC, or megaloblastic anemia, from ineffective erythropoiesis. Vitamin B6 and B12 are cofactors also involved in erythropoiesis [73].

20.12.2 Methionine Metabolism

Methionine metabolism occurs predominantly in the liver tissue with two components: a transsulfuration pathway, involving homocysteine reduction to glutathione, and a transmethylation cycle with folate and methyl nutrients producing *S*-adenosylmethionine (SAMe). Thus, methionine metabolism is dependent on dietary intake of vitamins B12, B6, and folate. SAMe is key in regulating epigenetic expressions of multiple pathways and, when deficient, leads to ramifications of nutritional and immune injury [74] (see ▶ Chap. 17).

20.12.2.1 Phytonutrients

Inflammation: powerful pigment-rich polyphenols found in a variety of fruits, vegetables, grains, nuts, teas, herbal spices, and legumes have anti-inflammatory properties. Plant chemicals include antioxidants and antibacterial and antiviral mechanisms. Even though phytonutrients are not considered essential nutrients, the evidence is mounting of their critical role health maintenance and anti-aging.

Biomarkers of phytonutrient status: poor dietary intake of high polyphenol foods. Significant biomarkers for inflammation can be related to poor vegetable and fruit intake and lack of or imbalance in dietary intake of healthy fats and oils (see ▶ Chap. 57).

Resource: The Rainbow Diet. Color Can Heal Your Life [75]

20.12.2.2 Minerals: [76]

Zinc critical role in the function of immune cells

Potassium principal intracellular cytosol electrolyte

Iodine thyroid hormone structure, brain development

Selenium thyroid peroxidase metabolism with vitamin E, selenoproteins special effects on cellular immunity resistance to viral infections. Central to glutathione peroxidase structure

Iron weaken cell-mediated immunity; decreases in neutrophil action

Magnesium co-factor in >300 enzymes affecting all systems

20.13 Key Lifestyle Factors Influencing the Risk of Infectious Disease

20.13.1 Sleep (see ▶ Chap. 45)

Sleep and circadian rhythm have a great influence on the integrity of the immune system. Much evidence has accrued over the past decades associating poor sleep quantity and quality with weakening of the immune system, increasing vulnerability to infection.

20.13.2 Stress (see ▶ Chap. 47)

Chronic stress impacts every biological and psychological system. The chemical microenvironment under long-term stress pushes the immune system response into chronic inflammation. The vicious cycle continues until the threshold of resilience and adaptation is exceeded, leading to vulnerability to many chronic diseases including infection.

20.14 Movement (see ▶ Chap. 36)

20.14.1 Examples of Chronic Disease Connections with Infectious Disease

20.14.1.1 Heart Disease/Cardiovascular Association with Infectious Processes

- *Infectious risk*: *Chlamydia pneumonia*, group A *Streptococcus* [77].
- *Dental*: periodontitis, necrosis of the jaw.
- *Rheumatic heart disease*: [78].
- *Bacterial endocarditis* (cardiac inflammation and scarring triggered by an autoimmune reaction to infection with group A *Streptococci*).
- *Pancarditis* (involving inflammation of the myocardium, endocardium, and epicardium); follows pharyngitis infection without antibiotic treatment.
- *Rheumatic chronic disease*: mitral valve stenosis almost always originates from rheumatic conditions and expresses and perfusion insufficiency. Rheumatic conditions are highly associated with underlying infection [79]. A previous infective endocarditis should be ruled out if there are symptoms of unexplained fever, malaise, or weight loss [80].

20.14.1.2 Oncology

Etiology of cancer can be related to infectious disease.

Viral EBV, CMV. Herpes simplex, herpes zoster, HIV, HPV

Bacterial *H. pylori*, *Mycoplasma pneumoniae*

Fungal Candida, mycotoxins

Mycoplasma *M. pneumonia, M. genitalium, M. hominis, ureaplasma urealyticum, U. parvum*

Parasites trichinosis [81], blastocystis hominis, tropical parasites

20.14.1.3 Neurological

Alzheimer's disease Viruses of life-long carriage are typically asymptomatic, strongly associated immunologic, and virologic characteristics with Alzheimer disease neuropathology increasing amyloid plaque and neurofibrillary tangles (NFTs): herpes simplex virus-1 (HSV-1), long-term cytomegalovirus (CMV) [82].

Developmental plasticity Due to fetal and early childhood metabolic plasticity influences by the environment, negative toxic exposures and infectious processes in utero or in childhood can influence the risk of later chronic adverse conditions, especially noncommunicable disease (NCD). This fact has driven the public health drive for vaccination programs during the first year of birth [83]. The importance of maternal health nutrition status and free from infectious disease lays the foundation for fetal growth. Developmental epigenetics studies provide insight into the importance of epigenetic marks occurring in utero and recognition of new biomarkers to provide interventions for prevention and treatment [83].

20.14.1.4 Respiratory (see ▸ Chap. 52)

Acute respiratory infection can derive from viral, bacterial, or mold/mycotoxin exposure. The risk for an individual can be related to exposure environment and genotype (e.g., cystic fibrosis, alpha-1-antitrypsin, Wegener's granulomatosis). More extensive discussion on respiratory conditions and infection is presented in ▸ Chap. 52.

20.14.1.5 Autoimmune (see ▸ Chap. 49)

Autoimmune conditions are inflammatory. Ongoing research has identified genetic relationships with susceptibility to developing autoimmune conditions, but coexisting infections can contribute to the etiology of an individual's disease. The human leukocyte antigen (HLA) group of genes is highly associated with risk of developing autoimmunity. HLA DQ2 and HLA DQ8 reside within the HLA gene group, and are known risks for developing celiac disease [84].

Comprehensive Human Leukocyte Antigen Panel

LabCorp Specialty Labs

20.14.2 Vaccination

During the twentieth century, the discovery and use of antibiotics began the breakdown of natural microbiota throughout the gastrointestinal tract and other microbiome-containing orifices. It is recognized at the time of this publication that the current epidemic of "superbugs" has resulted from overuse and misuse of antibiotics and antimicrobials. After the discovery of antibiotics, more pharmaceuticals were discovered to be providing strong manipulation of body systems and perturbing nutrient functions, such as steroid medications weakening connective tissue resulting in the increased need for vitamin C, biotin, and zinc. In addition, after World War II, there was the introduction of many "new-to-nature" molecules to agricultural practices and as additives to the food supply [85]. All of these new introductions into the human environment have altered the immune system, contributing to weakening defense systems. The twenty-first century is introducing even more organic and inorganic molecules that need more extensive investigation about their safety.

Two examples of concern:

1. *Fecal microbiota for transplantation* (FMT) implanting foreign bacteria from a donor into the gastrointestinal tract of a patient. The US Food and Drug Administration (FDA) has not officially approved FMT procedures but supports the area of scientific discovery. In 2019, implants performed for two immune-compromised patients from a single donor contained drug-resistant organisms. One of the patients died. Clinical trials were suspended and the FDA has warned all fecal matter for FMT should be tested for drug-resistant bacteria [86, 87]. This event illustrates the potential risk of FMT as a source of life-threatening infections.
2. *Vaccinations* have strong pro and con public opinion, but all sides agree in vaccine safety monitored by the US FDA and the *Centers for Disease Control and Prevention* (CDC). The principle of vaccination is based on the body's healthy adaptive immune response when exposed to a pathogen to develop protective antibodies to the pathogen. The most prominent concerns about vaccine safety are the additives to the vaccine preparations for preservation and effectiveness, the age at which vaccine is administered, and the number of vaccines given simultaneously. The most commonly used preservative adjuvants are aluminum, mercury-containing thimerosal [88], and formaldehyde. These compounds have known adverse effects. In 2011, the *International Agency for Research on Cancer* (IARC) named formaldehyde "a known human carcinogen" [89]. The US FDA has a reporting site for *Vaccine Adverse Event Reporting System* (VAERS) and *Wide-ranging Online Data for Epidemiologic Research* (WONDER) to provide public health information [90].

Thimerosal contains mercury, of which the *World Health Organization* (WHO) says that exposure, even in small amounts, "may cause serious health problems and is a threat to the development of the child in utero and early in life." "Mercury is considered by WHO as one of the top ten chemicals or groups of chemicals of major public health concern" [91]. Aluminum is a known neurotoxin and can play a significant role in neurological diseases. Reported elevated levels of aluminum found in Alzheimer's patient brains increases public concern. There is no evidence of harm for aluminum content in single vaccines, but concern for the accumulation of total aluminum in multiple-dose vaccine vials is not known.

The use of vaccines has become a highly debated political issue with states overhauling fundamental changes in their vaccine laws toward mandatory vaccination. Integrative and functional medical practitioners tend to embrace "first do no harm" and at least recommend parents base their decisions with full knowledge of the pros and cons of vaccinations for their individual child. There is no clear evidence of why some children and adults have mild to life-threatening side effects after receiving a vaccine.

If there is a suspected reaction to a vaccine, the *National Vaccine Injury Compensation Program* (NVICP) exists to provide financial compensation to individuals who have documented injury [92].

General considerations for parents that may increase vaccine safety for a child:

- Is my child sick the day of a scheduled vaccine? If yes, best to reschedule.
- Has my child had a reaction to any previous vaccination?
- Do our family or I have a history of vaccine reactions, neurological disorders, or immune system conditions like Sjogren's, lupus, celiac, eczema, etc.? If yes, document your child's personal and family history [90].
- What are the vaccination laws in the state in which I live?

If agreeing to vaccination, recommend limiting vaccinations to one vaccine administration at a time instead of multiple vaccines. Single-use vials of vaccines, if available, can be considered to reduce exposure to preservatives like thimerasol (mercury-containing) and formaldehyde.

Genomic counselors can be sought to discuss currently identified *single-nucleotide polymorphisms* (SNPs) that may be associated with increased risk of vaccine reaction.

Ensure your child is in good nutrition status, eating a balanced whole-food, low-pesticide, fruit- and vegetable-rich, low-sugar diet with adequate intake of vitamins D, A, and C, essential fatty acids, and bioactive forms of B vitamins from food or supplements if needed.

The US FDA has a reporting site for *Vaccine Adverse Event Reporting System* (VAERS) and *Wide-ranging Online Data for Epidemiologic Research* (WONDER) to provide public health information [90].

Several reports have shown that vitamin A deficiency results in a poor response to immunization, with generally low antibody responses to immunization with T cell-dependent antigens [93, 94].

20.15 Conclusion

This chapter reviews the importance of considering infection as a potential contributor to the etiology of any of the chronic diseases.

Infection can contribute to each type of chronic disease. Growing evidence is emerging that infections are most damaging to tissues and metabolism when they have continued as a prolonged burden on the immune system. Pathogens are generally attracted to specific tissue types and the disease that may develop for a unique individual may vary. Chronic diseases are characterized as long-latency, lifestyle, and diet-related diseases. An acute infection may either be resolved by a healthy immune system or survive and continue as a subclinical infection that is often not recognized but continues to wear on the immune system. Examples of commonly recognized subclinical infections that lead to increasing risk of a serious chronic disease: HPV risk of cervical or head/neck cancers, hepatitis C risk of liver cancer, Epstein-Barr virus risk of non-Hodgkin's lymphoma and some autoimmune conditions, and *C. pneumoniae* implicated in chronic illnesses, such as atherosclerosis, asthma, arthritis, multiple sclerosis, and many others. This chapter has described the association between a person's nutritional status and their vulnerability to infection. Individual nutritional status is a determinant of how well their body can respond to and resolve an infection, returning it to a state of wellness. The risk to get or not resolve an infection is greater from a compromised immune system when nutrient tissue levels are not optimized for an individual or able to provide adequate nutrient metabolic cofactors. Healthy nutritional status decreases risk of chronic diseases and vulnerability for long-latency prolonged infection [1, 3].

The healthy human body is equipped with defense features from conception throughout life to interact with the environment to protect from infection. Much of the defense starts with the skin barrier and microbiome at all body orifices to protect from pathogens entering and infecting. Another key is keeping the stomach acid-neutralizing pathogens or toxic organics from traveling further down the gastrointestinal tract where they could cause havoc and alter the powerful GI microbiome. These defenses guard pathogens and toxins from entering the blood and/or lymph circulation. Along with the internal milieu of the body, ethnic cultures have developed mores to support immune defense by traditions of toileting, diet, sleeping, sanitation (especially for food preparation and handwashing), and other complementary routines that minimize infection.

A growing recognition of the evidence of the pathophysiology of chronic disease reveals its contrast to acute disease by the long-term development often asymptomatic and not recognized. Subclinical infections can "smolder" unrecognized for many years, even beginning in utero and childhood, a stress on the immune system that often goes undiagnosed or there is unawareness of their significance. This chapter provides knowledge of assessment principles and specific immune-support nutrients and herbal components that can intervene if infections are identified. The increased clarity of scientific evidence supports "you and your genes are what you eat, digest, eliminate, sleep, move, avoid significant toxic exposure and live in a healthy relationship community" to live a long life that is vital and resilient and functional [95].

21.1 Introduction

Anthropometric measurements, such as body size, weight, and proportions, are often used to evaluate and monitor the effects of nutritional interventions as well as reflect an individual's overall growth and development. Body composition is the proportion of fat, muscle, bone, and water that make up the human body and its measurement helps determine excesses or deficiencies of a component that is related to health risk. In the fitness and sports setting, body fatness is an indicator of physical fitness and may be assessed by personal trainers and athletic coaches since fat content can affect sports performance. Nutrition practitioners often assess body composition since certain proportions are associated with a variety of health problems. Obesity and the newer identification of sarcopenic obesity of increased body fat percentage and loss of muscle, independent of BMI, has been associated with a number of diseases such as type 2 diabetes, hypertension, heart disease, arthritis, autoimmunity, liver disease, cancer, and kidney disease.

At the other end of the spectrum, too little body fat is often seen in those with eating disorders, oligomenorrhea, exercise addiction, and certain diseases such as cystic fibrosis, Crohn's disease, and cancer. Since physiological dysfunction can occur with too much or too little body fat, sarcopenic obesity and its distribution in the body, assessment and monitoring of body composition has become widespread and important for health practitioners (Fig. 21.1).

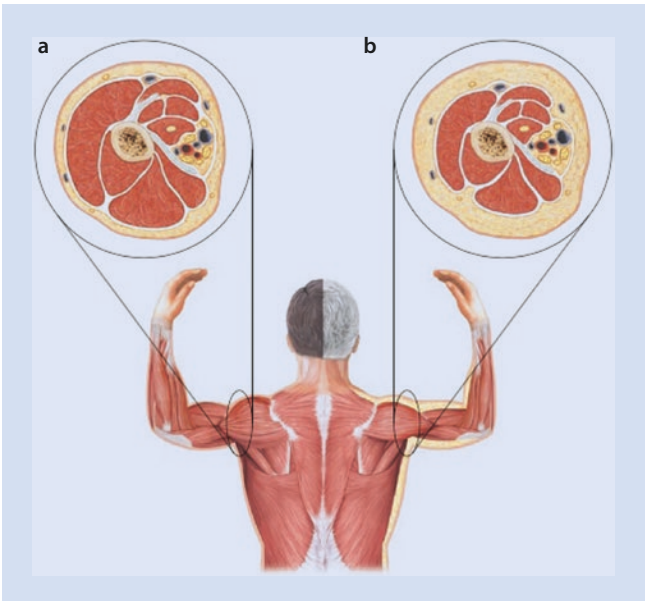

Fig. 21.1 Body Composition Changes with Sarcopenic Obesity. As people age they lose the lean muscle mass gained in young adulthood **a**, resulting in a higher proportion of fat mass **b**, even if the absolute amounts of body fat remain constant. This can lead to sarcopenic obesity – a loss of muscle and a concomitant increase in fat, often while the body weight remains stable or even decreases (Illustration by Anne Rains). (Reprinted from Benton et al. [1]. With permission from Wolters Kluwer Health)

Current methods for body composition assessment are characterized from simple to complex and all have some degree of measurement error. Some inherent problems with assessment techniques occur with the methodology, interpretation of data, and assumptions made with certain methods. The choice often depends on the intended purpose, cost, and available technology.

» Although decreases in muscle and increases in fat mass are considered part of the natural course of aging, to a great extent they're probably the results of inactivity and sedentary behaviors. – Melissa Benton [1]

21.2 Body Composition Methods

There are a variety of techniques used to estimate body composition as part of a nutritional assessment in the clinical setting. With all methods, strict adherence to the established protocols must be followed to obtain the most accurate results possible. Knowing the advantages and disadvantages of each method will help the practitioner decide wisely when choosing a method for body composition assessment.

One prevalent system of assessment is the two-compartment model, which assumes the body is made up of fat and fat-free compartments. The terms "fat-free mass" and "lean body mass" are often used incorrectly. Fat-free mass does not contain lipids, whereas lean mass includes approximately 2–3% for men and 5–8% for women. The lipids contained in lean mass include essential fat that serves as a structural component of cell membranes. Thus, the fat-free compartment is primarily made up of bone, muscle, other fat-free tissue, and body water. The water content of fat-free mass is about 72–74%. Except for cadaver studies, which provide a direct assessment of body composition, the methods discussed in this chapter are considered indirect measures and are appropriate for the clinical setting.

21.3 Field Methods

Field methods are commonly used for assessing body composition in both sport and health settings. Health practitioners use body composition in the assessment of nutritional and growth status, as well as in disease states and their treatment. Most measurements of body composition are made in the field or clinic, while more expensive laboratory methods are used primarily in research and for establishing the accuracy of the field methods [2]. Selecting a method is often difficult since practitioners want simple, inexpensive, and non-invasive options to measure body composition, but not at the expense of accuracy. Clinicians need to consider all factors and choose one or more methods that appropriately meet their needs.

21.4 Height, Weight, and Body Mass Index

Since loss of height may indicate certain health problems, the accuracy of the information on height is relevant for clinical practice. Measure stature, or height, using a wall-mounted stadiometer, or height rod, rather than asking the person his or her height. The wall-mounted measuring devices are preferred to the moveable rod on a platform scale, which lacks rigidity and can yield inaccuracy. Measurement of height can also be helpful in monitoring height loss in older individuals. In a recent study, the best predictors of a height loss of 3 cm or more were age, vertebral fractures, thoracic kyphosis, scoliosis, back pain, and osteoporosis [3]. Height loss may also be a useful tool in detecting vertebral fractures, low bone mineral density, and vitamin D deficiency [4].

Body weight should be measured using a standard physician's balance beam scale or a portable digital scale, which are accurate and consistent [5]. There is some belief that strain gauge scales may be more accurate than a conventional spring-type scale that simply has electronics to convert the result to a digital readout. Strain gauge scales use a strain gauge transducer to measure weight and display it digitally. This type of scale is inexpensive, accurate, reliable, and often portable. All scales should be placed on a flat, hard surface and checked for accuracy two times per year by using standard weights or the manufacturer recommended calibration methods.

From height and weight, body mass index (BMI), or Quetelet index, can be calculated and is a widely used clinical assessment to determine appropriateness of a person's body weight. It is currently the accepted method for interpreting the height-weight relationship and is commonly used in obesity research. BMI is calculated by dividing the weight in kilograms by height in meters squared. Although this is a quick and easy method for classifying weight, it does not assess actual body composition or distinguish between fat and muscle components. BMI tends to overestimate body fat levels in lean, muscular, or large-framed individuals, classifying them as overweight or obese [6]. A simple adjustment has been proposed that will allow the BMI of athletes to reflect the adiposity normally associated with non-athletic populations and provide the clinician or researcher with greater confidence when using BMI [7]. Body mass index also may not accurately reflect obesity and health risk in people with normal BMI values, but have a high percentage of body fat and visceral fat, especially among different ethnic groups [8]. Health practitioners should be aware of the limitations of using body mass index as the only assessment of body composition (Table 21.1).

Table 21.1 Body mass index

Body mass index (BMI) = body weight (kg)/height (m)^2
To determine body mass index, measure height to the nearest half inch and multiply by 0.0254 (to convert it to meters). Record weight to the nearest half pound and divide by 2.2 (to convert it to kilograms).

BMI	Classification
Under 18.5	Underweight
18.5–24.9	Normal
25.0–29.9	Overweight
30.0–34.9	Obesity – Class I
35.0–39.9	Obesity – Class II
≥40.0	Obesity – Class III (extreme obesity)

Based on data from Ref. [9]

21.5 Girth Measurements

Several body and limb circumferences are often used to estimate body composition and describe body proportions. These methods provide quick and reliable information and are often used to track changes in body size during weight loss interventions. There are also consumer apps available for smartphones that often use circumferences to estimate body fat, but these give little direction about how to accurately measure. Some common circumference sites and measurement tips are as follows:

- Wrist – Measure the minimum circumference of the wrist (the tape may need to be moved up and down to identify the minimum circumference).
- Forearm – This girth is measured at the maximal circumference of the forearm, usually closer to the elbow.
- Upper arm – Measure at the midpoint between the acromial (bony part of the shoulder) and the olecranon (bony part of elbow) process.
- Waist – Measure at the midpoint between the lower margin of the last palpable rib and the top of the iliac crest.
- Abdomen – Measure the torso at the level of the umbilicus.
- Hips – Measure the maximal circumference of the buttocks above the gluteal fold (measure from the person's right or left side to better identify maximal circumference).
- Thigh – Measure the largest circumference of the right thigh just below the gluteal fold.
- Calf – Measure at the largest circumference of the calf.

How to take measurements:

1. The person to be measured should wear minimal or tight-fitting clothing.
2. Take all measurements on the right side of the body when measuring limb circumferences.
3. Obtain the measurement with the tape in contact with, but not compressing, the skin.

4. Take waist measurements at the end of a normal expiration.
5. Take hip, thigh, and calf circumferences from the left or right side of the individual to ensure the tape measure is horizontal and parallel to the floor.
6. Record measurements to the closest line marking (i.e., fraction of an inch/cm).
7. Take each measurement is two times to ensure accuracy.

21.5.1 Waist Circumference (WC)

The measurement of waist circumference assesses an individual's pattern of fat distribution and visceral fat. In fact, obesity defined by waist circumference may be a better predictor of coronary artery calcification than BMI according to a recent study [10] that also showed those with BMIs in the overweight range and waist circumferences in the obese range had the second highest risk. Typically, waist circumference greater than 35 inches (88 cm) in women and greater than 40 inches (102 cm) in men significantly increases the risk for obesity-related diseases and may be a better predictor of the insulin-resistant phenotype and diabetes than BMI [11].

21.5.2 Waist-to-Hip Ratio

Waist-to-hip ratio (WHR) helps determine an individual's pattern of fat distribution and whether or not that pattern carries additional health risks. An excessive amount of visceral fat ("apple-shaped" bodies) has been associated with disorders of carbohydrate and fat metabolism and possible hypertension. Waist-to-hip ratio is also a marker of insulin resistance and hyperinsulinemia, which may assist the practitioner with recommendations for further laboratory testing. High insulin has been associated with increased risk of breast cancer and poorer outcomes after diagnosis. Elevated waist-to-hip ratio has been confirmed as a predictor of cancer mortality [12]. In one study, waist-to-hip ratio was a better predictor of obesity-related gastroesophageal reflux disease, also known as GERD [13]. Waist-to-hip ratio appears to be a better indicator for central body fat, regardless of waist circumference in patients with non-alcoholic fatty liver disease [14]. Those individuals with a healthy BMI or body fat percentage, but a high waist-to-hip ratio should be advised to further reduce overall body fat.

Calculate waist-to-hip ratio by dividing the waist girth by hip girth (waist ÷ hip). The World Health Organization (2008) has determined that a WHR of greater than 0.85 in women and greater than 0.90 in men shows an increased risk of metabolic complications.

21.5.3 Waist-to-Height Ratio (WHR)

Recent research has identified waist-to-height ratio (waist circumference more than half of your height) is considered as a simpler and more predictive indicator of early health risks associated with central obesity [15]. The use of waist-height ratio in public health screenings, with appropriate action, could help add years to life, according to a recent British study [16] and supports the simple message "keep your waist circumference to less than half your height." Waist-to-height ratio is a simple, quick, non-invasive method of assessment using measurements in centimeters or inches. The nutritionist should consider it as part of a standard assessment.

Waist-to-Height References (cm or inches) – ▶ omnicalculator.com

- Extremely slim – <0.34 both for men and women
- Healthy – 0.43–0.52 for men and 0.42–0.48 for women
- Overweight – 0.53–0.57 for men and 0.49–0.53 for women
- Very overweight – 0.58–0.62 for men and 0.54–0.57 for women
- Morbidly obese – >0.63 for men and > 0.58 for women

21.5.4 Upper Arm Circumference

Recently, some studies have shown the association of disease, biochemical changes, and nutritional status with upper-arm composition [17], which may provide a better assessment of muscularity and adiposity over other anthropometric measures, although it may not show short-term alterations in body composition [18]. One study found the combination of upper arm circumference and BMI good indicators of adiposity and showed arm circumference as a single measurement as a practical and good choice, correlating well with air displacement plethysmography [19]. Another study showed favorable results when predicting fat percentage using electrical resistivity of the upper arm [20]. Further research is needed to develop reliable normative data.

21.5.5 Using Circumference Measurements to Calculate Body Fat Percentage

One older formula (Katch, McArdle 1983) can be used to estimate body fat percentage if the clinician is looking for an easy way to assess fat along with monitoring changes in circumferences. The formulas below are based on age and gender and can be adjusted for athletes. Although the "athletic" adjustment was not defined for this formula, the practitioner can use the adjustment factor if the person regularly engages in moderate to vigorous physical activity or strenuous sports.

- *Younger Women (17–26 years)*
  % Body Fat = (abdominal circumference × 1.34) + (thigh circumference × 2.08) – (forearm circumference × 4.31) – 19.6
- *Older Women (over 26 years)*
  % Body Fat = (abdominal circumference × 1.19) + (thigh circumference × 1.24) – (calf circumference × 1.45) – 18.4

- *Younger Men (17–26 years)*
  |% Body Fat = (upper arm circumference × 3.70) + (abdominal circumference × 1.31) – (forearm circumference × 5.43) – 10.2
- *Older Men (over 26 years)*
  % Body Fat = (buttock circumference × 1.05) + (abdominal circumference × 0.90) – (forearm circumference × 3.00) – 15.0

Athletic Adjustment Factor: Subtract 4.0 for males and 3.0 for females from the percent body fat value.

21.5.6 Skinfold Measurement

Skinfold measurement, the thickness of a double fold of skin and compressed subcutaneous adipose tissue, is widely used in the clinical setting. The validity depends on the accuracy of the measurement and the skill of the technician. An improperly trained technician will introduce significant measurement error. Skinfold calipers are used and a variety of measurements are taken from different sites on the body. Common sites for measurement include the triceps, biceps, subscapular, suprailiac, abdomen, upper thigh, and calf. There are several different protocols utilizing these sites that yield an individual's estimate of body fat percent. Though skinfold measurement yields a percentage of body fat, the individual site measurements may also be a good way to monitor patient progress. It should be noted that this is a somewhat invasive measurement, since the fat must be pinched and pulled away from the muscle. This can cause some discomfort and embarrassment in some patients and is inappropriate for those who are severely obese. Individuals will have variations in skinfold thickness, compressibility of tissue, and hydration level, which is likely to affect the measurement.

There are many assumptions involved in using skinfold measurement to predict body fat [21]:

- Skinfold compressibility is constant.
- Skin thickness is constant (subscapular skin thickness was found to be greater than skin thickness at other sites).
- Subcutaneous adipose tissue patterning is constant (there is variability reinforcing the importance of using readings from multiple sites).
- Variability in fat content of adipose tissue is constant (estimated to be 20%).
- Internal and subcutaneous fat deposition is constant.

Biochemical individuality plays a major role in the accuracy and reliability of this method. While skinfold measurement is not the optimal method for body composition assessment when time and accuracy is a concern, practitioners should be aware of this technique, which has been widely used in a variety of health and fitness settings.

21.5.7 Bioelectrical Impedance Analysis and Bioimpedance Spectroscopy

Bioelectrical impedance analysis (BIA) is a non-invasive, useful tool for estimating body composition based on a two- or four-compartment model [22]. Numerous researchers have conducted studies on bioimpedance analysis and its applications in estimation of body composition and evaluation of clinical conditions [22]. This technique measures the resistance, called impedance, to a small electrical current as it travels through the body's water pool and is based on the principle that lean tissue has a higher electrical conductivity and lower impedance than fat tissue due to its electrolyte content relative to water. With this method, the instrument generates an alternating electrical current, which is passed through the body via electrodes that are either placed on the body or built into a scale or handheld instrument.

Bioimpedance spectroscopy (BIS) is known as full-body (hand-to-foot) multi-frequency BIA as it allows total body water to be differentiated further into intracellular and extracellular water compartments. This is useful when monitoring fluid shifts and hydration. BIS can also provide an estimate of body cell mass (BCM), an important indicator of nutritional status. BIS differs from the more widely recognized single-frequency BIA and does not require the use of statistically derived, population-specific prediction equations [23]. Some BIA instruments use the multi-segmental approach, which assumes the body is made up of a group of cylinders (left and right arms, left and right legs, and the total body) and are available in both single-frequency and multi-frequency systems.

The BIA is widely used in practice and body composition research. Its benefits of BIA include its portability, ease of use, low cost (depending on the instrument), and safety. It measures impedance with high precision, does not subject the person to ionizing radiation, and requires minimal subject involvement. It is useful in the clinical setting provided the individual follows important pre-test instructions:

- Avoid heavy exercise for 12 hours before testing.
- Refrain from consuming caffeine and alcohol the day before testing.
- Maintain good hydration (dehydration will overestimate fat mass).

Limitations of the BIA include poor accuracy in estimating fat-free mass and percent body fat, with the trunk being under-represented and the limbs over-represented [24]. Since BIA instruments rely on regression equations for their calculations, the method is good only if the appropriate equations are used. This is the reason why some instruments are better than others ranging from inexpensive, portable BIA scales to professional and expensive devices. These units can range in price from $50 to $30,000 (Figs. 21.2 and 21.3).

Bioelectrical impedance analysis has shown to be efficacious in assessing body composition in patients with eating

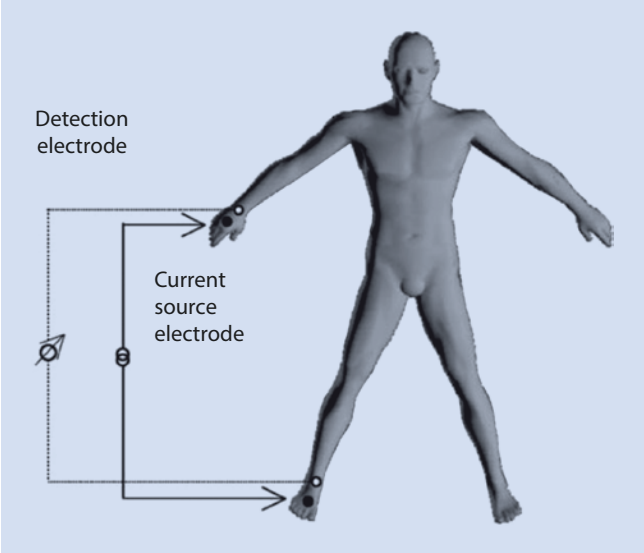

Fig. 21.2 Bioelectric Impedance Analysis standard placement of electrodes on hand-wrist-foot and ankle for tetrapolar single (SF-BIA) and multiple-frequency (MF-BIA) BIA. (Reprinted from Kyle et al. [25]. With permission from Elsevier)

disorders during the treatment period [27], since only assessing weight changes does not reflect changes in various body compartments. BIA was studied as a tool to measure fluid changes in obese patients after bariatric surgery, but researchers found it impractical in the clinical setting for extremely obese patients due to individual variability [28].

BIA can also yield very beneficial information when used in wheelchair bound and bedridden [29] paraplegic and quadriplegic individuals and other special populations, especially when cognition or speech is impaired so a patient history cannot be reported for dietary and fluid intake.

21.6 Bioelectrical Impedance Analysis: Non-body Composition Parameters for Nutritional Assessment

In addition to body composition measurement, the bioelectrical impedance analysis (BIA) is also an important functional tool in evaluating the metabolic status of a patient. It provides data about body cell mass, cell membrane fluidity, and cell electrical potential.

Body cell mass (BCM) contains metabolically active components of the body such as muscle cells, organ cells, blood, and immune cells. BCM also includes intracellular water and the active portion of fat cells, but not the stored fat lipids. Since BCM is the functional mass of the body where most of the metabolic work is done, it is an indicator of overall nutrition status. In well-nourished individuals, the muscle tissue accounts for approximately 60% of the body cell mass, organ tissue for 20%, and the remaining 20% made up of red cells and tissue cells. When the body cell mass increases, it indicates an increase in muscle tissue. A body cell mass of about 40% is desirable.

Phase angle (PA) is a general indicator of overall health and is a measurement of cell membrane integrity and often referred to as a marker of cell membrane fluidity. "Phase angle (PA) is interpreted as an indicator of cell membrane integrity and a prognostic indicator in some clinical situations [30]." Without universal references available, and general recommendations developed from BIA research and clinical observation, a PA of 6–8 is optimal. As the membrane becomes rigid, receptor function and healthy exchange between intracellular and extracellular compartments decrease. Lower phase angles (<6.0) are consistent with an inability of cells to store energy and can indicate a breakdown in the permeability of cellular membranes. Since cell membranes have a high lipid content, phase angle provides an indication about lipid status. Low phase angles may reveal insulin resistance, malnutrition, infection, chronic disease, cancer, perturbed fatty acid status, reduced antioxidant status, and old age. Higher phase angles (>8.0) can be consistent with intact healthy cell membranes and body cell mass. Frequent clinical observation of higher phase angles is seen in those who exercise and consume a healthy diet, including antioxidant-rich fruits, vegetables, and healthy fats. Higher than 8 is excellent and 6 or lower can indicate a serious energy deficiency or chronic disease state.

Body Capacitance (C) is an indicator of the cell wall ionic potential, the ability of the non-conducting object to save electrical charges. All movement of energy and compounds require biochemical ionic charge. This value is primarily dependent on nutritional influences of mineral electrolytes and potential of hydrogen (pH) on establishing

the capacitance (C), which is the ability of the non-conducting object to save electrical charges. When capacitance or electrical charges are low, it has clinically been beneficial to check the individual's mineral status (serum electrolytes, calcium, magnesium, and blood pressure). If the person's condition clinically supports low mineral status, consider increasing dietary sea salt and magnesium, and reduce calcium intake, if elevated. If capacitance is high, it is suggested to check serum calcium, electrolytes, blood pressure, and dietary intake of calcium. Oxidative stress, free radical damage, toxicity, and low antioxidant reserve also affect this result. Optimum numbers reflect a healthy cell. The body capacitance number can move up or down rapidly. Optimum capacitance for males is about 1300 and for females is about 900.

It is important to note regarding inverse relationships with calcium and other nutrient minerals with RBC and urine excretion testing results. Calcium is primarily an extracellular element because cells carefully regulate its entry into the cell. When BIA capacitance readings occasionally measure higher than optimum reference, it can be inferred that there may be a high calcium-to-magnesium and potassium ratio.

Total Body Water as a percentage of fat-free mass is a marker of hydration. If this result is <69% the patient should be put on hydration protocol and retested in 24–48 hours as values below this level indicate dehydration. This is an accurate indicator of hydration even when the person is significantly overweight.

Total Body Water (TBW/total weight) as a percentage of total weight can show dehydration but is also related to percentage of body fat. If a person's percent fat falls in the overweight or obese categories, then consider the inverse relationship between total body fat and TBW (total body water may show lower values). This is due to lean body mass being approximately 70% water and body fat being around 10% water. This value may decline with age.

Consumption of food or beverages in preparation is important to consider with the recommendations as food or fluid intake before BIA measurement affects TBW and ECW from studies in the 1990s.

» Significant alteration in body hydration, fluid distribution, and differences in the ratio of ECW to ICW caused by a medical condition will affect impedance measurements. Among those conditions, the most significant confounding variable is edema of the distal extremities, which is mainly caused by peripheral venous insufficiency. This insufficiency may result from congestive heart failure, cirrhosis, nephrotic syndrome, hypoalbuminemia, and lymphoedema [31]. Other medical conditions, which affect BIA validity, include cutaneous disease that may alter electrode-skin electrical transmission in patients with amputations, poliomyelitis, and muscular dystrophies. These conditions will have significant effects on the application of BIA in the clinical population [25].

21.7 Intracellular Water (ICW)/Extracellular Water (ECW) Hydration

The assessment of extra-, intracellular, and total body water (ECW, ICW, TBW) is important in many clinical situations [32]. For the nutritional perspective to be clinically useful, it is important to review the physiology of ICW and ECW. ICW is 97% potassium and ECW 97% sodium and calcium. The homeostasis between the two compartments is regulated by the action of the sodium-potassium pump (Na^+/K^+ pump) that was discovered in 1957 by Danish scientist Jens Christian Skou. The pump is an active process driven by the energy of ATP with magnesium being the primary driver of the pump. Thus, these three mineral-electrolytes become a focus when assessing nutritional balance of the cellular compartments, pumping potassium into cells while pumping sodium out of cells against their concentration gradients. The Na^+/K^+ pump supports maintenance of the resting potential affecting transport between the compartments while regulating cellular volume. Magnesium status of an individual is an important consideration in assessing a person's nutrition status since magnesium is important to the function of the pump. NHHANES studies have repeatedly identified that about 80% of the U.S. population consumes less than the RDA of magnesium (NHHANES).

The Na^+/K^+ pump has many functions with some of the most important the import of glucose, amino acids, and other nutrients into the cell using the energy of the sodium gradient.

Thus, the individual's data of ICW and ECW from a BIA measurement can be supportive of further investigation of mineral-electrolyte status with biomarkers in blood testing like: RBC minerals (magnesium, calcium, potassium), electrolyte panel and urinalysis-specific gravity, along with nutrition physical exam of skin assessing potential edema or dehydration issues (see ▶ Chap. 39). Assessing the dietary history for intake of magnesium and potassium-rich foods, and salt and high-sodium food intake can provide guidance, if needed, to improve better balance of these mineral-rich foods. Assessing intake of fatty acids and phospholipid-rich foods is also valuable to consider cell membrane fluidity influencing the activity of the Na^+/K^+ pump. During development of the nutrition intervention plan for an individual, improving the dietary intake (food, fluids, and potential supplements) based on the hydration measurement markers of the BIA ICW and ECW status can affect physiological function of all cells. Repeated BIA testing during monitoring and evaluation of a patient demonstrates if the nutrition intervention is effective in improving cellular hydration (◘ Fig. 21.4).

Basal metabolic rate (BMR) represents the estimated number of calories metabolized at rest during a 24-hour period. About 70% of a human's total daily energy expenditure is due to the basal life processes within the organs of the body. About 20% of one's energy expenditure comes from physical activity and another 10% from ▶ thermogenesis. BMR decreases with age and the loss of lean body mass and

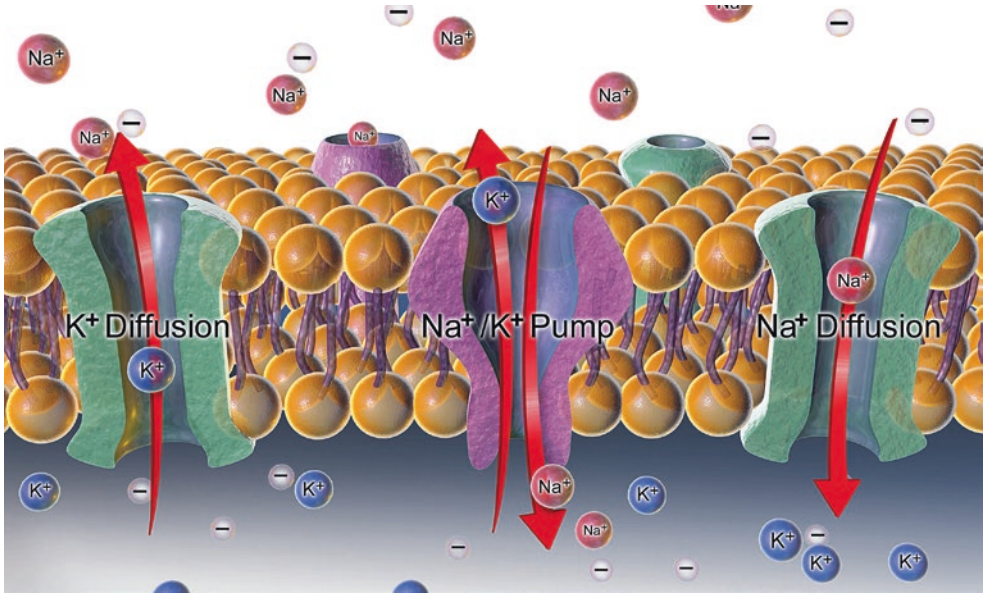

Fig. 21.4 Sodium-potassium pump. The Na+/K+-ATPase, as well as effects of diffusion of the involved ions maintain the resting potential across the membranes. (Reprinted from ► Blausen.com staff [26]. With permission from Creative Commons License 3.0: ► https://creativecommons.org/licenses/by/3.0/deed.en)

increases as lean body mass increases, since lean mass is metabolically active. The BMR value is important for providing patients with estimated daily calorie intake plus caloric need adjustments for physical activity or energetic requirements (like infection).

21.8.1 Electrical Impedance Myography

Electrical impedance myography (EIM) is a technique for the evaluation of neuromuscular diseases that may have future significance for the measurement of body composition. EIM technology is similar to bioelectrical impedance technology in that it sends an electrical current into the limb (usually arm or leg), but unlike BIA devices that send a current through lean mass, EIM measures how current flows through muscle and fat tissue. A new consumer product, Skulpt®, was recently introduced as a way to measure muscle quality along with body fat percent to help people monitor progress during exercise training. Muscle quality is defined as the force a muscle produces relative to its size and is a scientific metric for the fitness of muscles. This could have clinical significance not only for sports enthusiasts, but also for those with chronic diseases.

In addition to muscle quality, the device measures overall fat percentage and local fat percentage in 24 different areas of the body. The device was originally made to monitor muscular degeneration disorders, but using a complex algorithm that does not require age, gender, or weight, the device can estimate overall body fat percentage as well as in local areas. The company manufacturing the Skulpt® device was founded in 2009 by Dr. Seward Rutkove, a Harvard Medical School neurology professor, and Dr. Jose Bohorquez, an electrical engineering graduate from Massachusetts Institute of Technology (MIT). Most of the research involves EIM's use in neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) and muscular dystrophy. Internal research by the manufacturer on body composition shows a high correlation when compared with dual-energy X-ray absorptiometry (DEXA) measurements. Since this is the only device on the market that measures muscle quality, it may have important clinical significance for health practitioners. Although further research is needed, practitioners may consider using this low-cost device (about $100) to monitor changes resulting from weight loss and exercise interventions. The Skulpt® device is designed to be used with smartphones or tablets and is extremely portable.

21.8.2 Consumer Apps for Smartphones

There are a number of smartphone apps for consumers to assess body composition. Many use circumferences, skinfolds, bioelectrical impedance technology, or are an extension of Wi-Fi-connected bathroom scales. Most allow users to track body mass index (BMI). While many of these do not provide a high degree of accuracy, the health practitioner may find these useful for monitoring client progress. In addition, clients may find such apps motivational, which may improve compliance with weight loss interventions.

21.9 Laboratory Methods

Laboratory methods for assessing body composition are used often in research or when evaluating athletes, but vary in their accuracy and precision [24]. Some of these methods are used as criterion to validate field methods. Health practitioners may consider selecting a laboratory method depending on the size of the clinic and the demographics of patients. For example, a dual-energy X-ray absorptiometry (DXA/DEXA) scanner may be chosen if the practitioner wants to assess and monitor bone mineral density in addition to body composition. The main disadvantage of laboratory methods is the high cost of the equipment.

21.9.1 Hydrostatic Weighing

A technique for determining whole body density is hydrostatic, or underwater, weighing. This method is based on Archimedes' principle, which states that the volume of an object submerged in water equals the volume of water it displaces. This method yields a more accurate estimation of body fat percentage and is considered the criterion method, but is impractical in a clinical setting. Hydrostatic weighing is based on the two-compartment model of body composition and assumes that fat-free mass has a constant level of hydration and a constant proportion of bone mineral to muscle. Other studies have shown the density of fat-free mass is not constant [34] and the variation in bone mineral density affects the density of fat-free mass. This technique also requires cooperation from the person being measured since he or she must be submerged in water and remain still long enough for an accurate measurement to be taken. Hydrostatic weighing remains the standard laboratory technique to which most other methods for assessing body composition are often compared.

21.9.2 Air Displacement Plethysmography

The fundamental principle behind the air displacement plethysmography (ADP) method for measuring body composition uses the inverse relationship between pressure and volume to measure total body densitometry. This method is an alternative to underwater weighing and is better tolerated by individuals. Air displacement plethysmography is determined by a commercially available product called the BOD POD®, which measures body composition in adults and children. The PEA POD® has neonatal applications. One advantage of this method is that it is more convenient and comfortable than underwater weighing and more practical in the clinical setting. In general, the air-displacement plethysmography method shows agreement between two other criterion methods (hydrostatic weighing and dual-energy X-ray absorptiometry); however, some studies show significantly different estimates of body composition. According to a recent study, clinicians using this method should perform two trials and report the average result [35].

Both air displacement plethysmography and hydrostatic weighing correlate remarkably well with computed tomography (CT) algorithms for measurement of body composition [36]. Of all the methods, air displacement plethysmography appears to be the best instrument for tracking body composition from infancy to adulthood, when compared to bioelectrical impedance, dual-energy X-ray absorptiometry, hydrometry, and magnetic resonance imaging [37]. This is likely because it is the only practical clinical tool available for use in infants.

21.9.3 Dual-energy X-ray Absorptiometry (DXA/DEXA)

Dual-energy X-ray absorptiometry (DXA/DEXA) was originally developed to assess bone mineral density and is currently considered the gold standard technique for the diagnosis of osteopenia and osteoporosis. Recently, it has become a widely used approach for determining fat mass and fat-free mass. It uses a three-compartment model rather than two-compartment measuring bone mineral density, fat, and fat-free soft tissue. DXA/DEXA is non-invasive, quick, and reliable, though the equipment is relatively expensive.

The International Society for Clinical Densitometry (ISCD) recently developed official positions regarding the use of the DXA technique for body composition analysis. The report limited indications to three conditions: HIV patients treated with antiretroviral agents associated with a risk of lipoatrophy; obese patients undergoing treatment for high weight loss; and patients with sarcopenia or muscle weakness [38]. However, DXA/DEXA offers diagnostic and research possibilities for a variety of diseases and has the potential to monitor body composition changes with various nutritional interventions. The ongoing National Health and Nutrition Examination Survey (NHANES) uses this technique for bone density and body composition assessment.

As with most methods for assessment of body composition, DXA/DEXA has some disadvantages and limitations. The radiation exposure from a whole-body scan ranges from 0.04 to 0.86 millirem, an extremely low dose when compared to the exposure of a standard chest X-ray [39]. For this reason, repeated, frequent measurements are not recommended. Other limitations include weight and height limits on the scanning bed with some units and the field of view cannot accommodate large individuals. Differences in the hydration of lean tissue may affect the results as well as trunk or limb thickness. Despite its limitations, some studies show it is more accurate than densitometry methods [40], which has led to the use of DXA/DEXA as a reference laboratory method.

When DXA/DEXA was compared to air-displacement plethysmography (BOD POD®), researchers concluded that the BOD POD® was more accurate when measuring people closer to a healthy BMI, but it was less accurate than DXA/DEXA when it came to measuring lean individuals [41]. Those with low body fat percentages were more likely to get a

higher percent fat reading from the BOD POD®, and people with higher body fat percentages were more likely to see a lower result. Both techniques had smaller discrepancies in normal weight and overweight individuals.

21.9.4 Medical Imaging – Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

Computed tomography (CT) scans are capable of estimating subcutaneous and intra-abdominal fat and compare closely with direct measurements in cadavers [42]. The disadvantages of using CT for assessing body composition include high levels of radiation exposure, cost, and limited availability of equipment. Magnetic resonance imaging (MRI) allows both imaging of the body and in vivo chemical analysis without ionizing radiation. It is a valuable tool for assessing regional fat distribution and muscle mass, but it is a costly method for health practitioners. Therefore, neither CT or MRI is practical for everyday body composition assessment.

21.9.5 Ultrasound

Ultrasound technology is a widely used imaging method and has been studied as a possible tool in nutritional assessment. It is a low cost, somewhat portable, alternative method for assessing body composition. In a recent study, when a specific regression equation was applied, ultrasound showed a strong correlation with DXA/DEXA [31]. Ultrasound can provide a similar degree of accuracy and reliability when compared with DXA/DEXA and air displacement plethysmography for tracking group-based body fat changes over time [43, 44]. One advantage of ultrasound is that it can provide information about fatty liver disease in obese patients and shows a high correlation with other markers such as waist circumference, trunk fat mass, and intra-abdominal adipose tissue [45]. In addition to assessment of body composition, ultrasound has also been suggested as a method for visceral fat mass evaluation. Estimates of total body fat based on ultrasound will result in higher accuracies when compared with skinfold measurements and bioelectrical impedance [24].

In the sport and athletic setting, ultrasound offers highly accurate and reliable field measurement essential for protection of the athlete's health and optimizing performance [46]. One study showed the validity of a portable ultrasound device questionable in female athletes, but due to its excellent reliability, practitioners and coaches should consider this method for assessing body composition changes [47].

21.10 Classification Based on Percent Fat

There are several different systems currently used for classifying body fat percent. The American College of Sports Medicine (ACSM) and American Council on Exercise (ACE) are among those most commonly used in fitness and are presented below. It should be noted that a certain amount of fat is essential for normal bodily functions. This is the fat in the bone marrow, heart, lungs, liver, muscle, and lipid-rich tissues throughout the body, including cell membrane. Essential fat in females is approximately 10–13% and in males is 2–5% (Tables 21.2 and 21.3).

Some classifications have been presented that are adjusted for age, since body fat often increases and lean mass decreases as part of the aging process. ACSM also offers age-adjusted norms for body fat percent and are presented in Table 21.4.

Once a person's body fat has been determined, the clinician can use the following equation to predict a healthy weight based on body fat percent. This equation assumes that the person's lean mass remains the same.

$$\text{Desired Weight} = \text{Current Fat} - \text{free Mass in pounds} \;/\; (1 - \text{desired\%})$$

Example:

- Female with a current percent fat = 31% and body weight of 170 pounds.
- 170 × 0.31 = 52.7 pounds fat mass
- 170–52.7 = 117.3 pounds of fat-free mass
- Her desired percent fat is 25% – (1–0.25) = 0.75
- *Add to the equation:*
- 117.3 (current fat-free mass) divided by 0.75 = 156.4
- 156.4 would be her desired weight (25%) if her fat-free mass remains the same

Table 21.2 ACSM body fat classifications

ACSM	Percent fat	
Body type	**Females (%)**	**Males (%)**
Athlete	<17	<10
Lean	17–22	10–15
Normal	22–25	15–18
Above average	25–29	18–20
Over-fat	29–35	20–25
Obese	>35	>25

Fitness category	**20–29**	**30–39**	**40–49**	**50–59**	**60+**
Essential fat	2–5	2–5	2–5	2–5	2–5
Excellent	7.1–9.3	11.3–13.8	13.6–16.2	15.3–17.8	15.3–18.3
Good	9.4–14	13.9–17.4	16.3–19.5	17.9–21.2	18.4–21.9
Average	14.1–17.5	17.5–20.4	19.6–22.4	21.3–24	22–25
Below average	17.6–22.5	20.5–24.1	22.5–26	24.1–27.4	25.1–28.4
Poor	>22.6	>24.2	>26.1	>27.5	>28.5

21.11 Conclusion

Body composition measurement helps determine excesses or deficiencies of components that relate to health risk. Significant changes in body composition are strongly correlated with the pathophysiology of chronic diseases. The importance of measuring body composition beyond height and weight anthropometrics is becoming increasingly appreciated in research and healthcare practices. The parameters of phase angle, capacitance, percentage of body fat, body cell mass, and distribution of water (ICW/ECW) provide beneficial data for assessment and developing intervention. Body fat percentage is one of the most appreciated body composition measurements, as evidenced by all chronic diseases exacerbated with the increase in body fat percentage and distribution of fat toward central adiposity. Whichever method is used to determine percent body fat, it is best for the practitioner to select that same method for repeat measurements. Some practitioners have experimented with the above techniques and measured themselves using a variety of methods, all within a 30-minute period. This type of experiment yields vastly different results, similar to what has been observed in research when comparing these methods to each other. Other body composition parameters also have valuable inferences about the health of the individual that can influence more effective interventions and monitoring of progress.

The field methods of body composition available are ideal for the nutrition practitioner whether using in-office full-body units or using the data from more expensive requiring equipment like *hydro-densitometry,* DXA/DEXA, Bod Pod, and Pea Pod that are considered for larger clinics or hospitals. The clinician should consider cost, ease of measurement, and ability to monitor progress in patients undergoing interventions.

Learning Objectives

1. Name at least two disease-promoting pathways that are downregulated through implementation of a therapeutic ketogenic diet.
2. Describe the steps that characterize the metabolic shift to ketosis.
3. Describe the rationale for use of a therapeutic ketogenic diet for expanded applications including (1) diseases of insulin resistance, (2) cancer, and (3) neurodegenerative disease.
4. Know what demographic and health history information must be included in order to begin a risk/benefit analysis.
5. Describe the calculations needed to develop an individualized macronutrient prescription for a therapeutic ketogenic diet.

22.1 The Current Paradigm

There is a pervasive belief that glucose is the optimal source of energy for the brain and central nervous system. However, the reliance on glucose to meet brain and central nervous system (CNS) energy requirements is only true if the intake of dietary carbohydrates is sufficiently high to keep homeostatic control of glucose dependent on the opposing actions of the hormones insulin and glucagon. When glucose availability is low—as it is during fasts or very-low-carbohydrate diets—cerebral energy metabolism shifts to the efficient utilization of ketone bodies. This makes evolutionary sense given the frequent disruption of the food supply that has marked most of human history prior to the transition from hunter-gatherer to agrarian societies.

The brain and CNS of most adults requires the *energy equivalent* of 130 g of carbohydrate per day. In a standard diet, it is assumed that this need will be met through the dietary intake of carbohydrates without considering the potential of ketone bodies as an energy source. This absolute requirement, designated as the Recommended Dietary Allowance (RDA), has been incorporated into a set of government guidelines known as Dietary Reference Intakes (DRIs) [1]. However, signs are appearing that government nutrition authorities are beginning to recognize that essential glucose energy is still available during ketosis:

> Diets contain a combination of carbohydrate, fat, and protein, and therefore available glucose is not limiting to the brain unless carbohydrate energy intake is insufficient to meet the glucose needs of the brain. Nevertheless, it should be recognized that the brain can still receive enough glucose from the metabolism of the glycerol component of fat and from the gluconeogenic amino acids in protein when a very low carbohydrate diet is consumed [1].

This statement acknowledges the *physiological fact* that very-low-carbohydrate diets will shift metabolism away from reliance on glucose obtained from exogenous sources. Subsequent to that shift, the majority of tissue with high energy needs, such as muscle, heart, and most brain tissue, will preferentially take up ketone bodies. During starvation or with adherence to a ketogenic diet, ketone bodies are produced in sufficient amounts to easily meet more than 60% of the energy needs of the brain and CNS. This amount was determined by a rigorous human fasting study conducted by Dr. George Cahill and colleagues, published in 1967 in the *Journal of Clinical Investigation* [2]. Unfortunately, most conventional nutrition texts either imply or implicitly state that the presence of more than trace amounts of ketone bodies reflects an invariably aberrant and potentially dangerous metabolic state. This fails to acknowledge the science supporting nearly a century of use of a therapeutic ketogenic diet as a medical nutritional therapy for epilepsy [3, 4].

The DRIs for glucose have been superseded by another set of government guidelines from the Food and Nutrition Board: the Acceptable Macronutrient Distribution Range (AMDR). The AMDR recommends that carbohydrate-containing foods make up 45–65% of total calories [5]: In a 2000 calorie-per-day plan, that percentage translates to an intake of 225–325 grams of carbohydrate, an amount far greater than the DRI. As previously noted, this recommendation is not due to the need for carbohydrate as an essential nutrient. Instead, it exists based on its role as a source of kilocalories to maintain body weight [6]. In fact, science makes clear that there is no requirement for dietary glucose even in populations with extremely high energy needs, such as ultra-athletes. A recent paper illustrates this point by stating: "less appreciated is the perspective that there is no essential requirement for dietary carbohydrate because humans possess a robust capacity to adapt to low carbohydrate availability" [7].

Key Point: Unlike Fat or Protein, Dietary Intake of Glucose Is Not Essential to Human Life

In the absence of sufficient dietary intake, glucose homeostasis is maintained at *normal physiological levels* primarily through gluconeogenesis: Glycerol backbones stripped from triglycerides as part of fatty acid oxidation become the major substrate with contributions from amino acid and the recycling of lactate through the Cori cycle.

22.2 Factors in Choosing an "Ideal" Diet

The ideal diet is one that ensures adequate nutrition, lowers inflammation, improves insulin sensitivity, and normalizes body weight. It must be sustainable long-term and flexible enough to accommodate food allergies, aversions, and intolerances. It must accommodate the fact that religious, cultural, and personally held beliefs, such as the philosophical decision to avoid all animal products, will influence food choices. Beyond the basics, though, there is no consensus as to what constitutes the ideal diet.

22.2.1 Genetic and Epigenetic Influences

Genetic variants can alter an individual's response to foods, even to those that are generally regarded as healthy. Traits such as lactose intolerance or glucose-6-phosphate dehydrogenase (G6PD) deficiency require the avoidance of certain foods or beverages. For example, the diet for an individual with lactose intolerance would limit milk and a diet for an individual with G6PD would exclude fava beans, sulfites, and quinine.

Changes in gene expression also arise from epigenetic influences. Interactions of genes with the environment may include but are not limited to those induced by environmental toxins (lead, smoke, radon, pesticides), lifestyle impacts (night shift work, poor sleep hygiene, food choices), and psychological stressors (chronic disease, unrelenting stress). Complexity increases when age, gender, nutritional insufficiencies, and comorbidities are factored into the situation. As a result, primary prevention might dictate one set of rules while tertiary care demands another.

Consuming certain foods can alter gene expression. The constituents in a food can turn on or turn off the signaling responsible for controlling vital activities at the cellular level. Research in the field of nutrigenomics is illuminating the impact of micronutrients and other food constituents while inquiry into the impact of dietary manipulation of macronutrients arises primarily from the study of biochemistry and physiology. One example is the abundance of research on the role of protein and constituent amino acids in regulating cellular pathways such as the mammalian (or mechanistic) target of rapamycin (mTOR) (see below). In muscle, the presence of abundant amino acids (particularly branched-chain amino acids) generally signals muscle tissue to increase anabolic activities that stimulate the accretion of muscle mass which is considered highly valuable. However, those same signals are also known to stimulate growth and proliferation in cancer cells characterized by upregulated mTOR activity. Changes in protein intake and meal timing are known to downregulate this activity but conventional cancer researchers remain focused on the development of drugs intended to inhibit this pathway. Unfortunately, these drug therapies, such as rapamycin, all have dire downstream effects.

It is understandable that the role of epigenetic influences in disease states is often overlooked as it involves the accumulation of numerous small changes occurring over years or even decades. Yet it is increasingly clear that these changes eventually tip the scales, causing an imbalance in the system that manifests as disease. This appears to be the case with insulin resistance, cancer, and neurological disease. As noted earlier, the interaction of genes with the environment is complex and multifactorial, which makes it exceedingly difficult to isolate which factors exert the most influence.

22.2.2 The Inflammatory Response

The production of inflammatory cytokines is an essential component of the immune response, but prolonged overproduction of these proteins may result from repeated exposure to antigens [8]. Inflammatory cytokines are also secreted by insulin-resistant adipose tissue. This is increasingly being shown to play a critical role in obesity-related insulin resistance, and it wreaks havoc in the form of chronic inflammation, a prime driver in many diseases. Chronic inflammation at any site damages cell membranes and DNA while simultaneously altering normal cell molecular signaling and repair mechanisms. The presence of ketone bodies lowers the levels of some of these cytokines. [9].

22.2.3 Insulin Resistance Adds Fuel to the Flames

In individuals consuming a standard diet (with carbohydrate intake of 45–65% of total calories) each meal or snack results in a significant rise in serum glucose, which in turn stimulates beta cells in the pancreas to secrete insulin. Over time, a persistent pattern of frequent spikes in glucose and insulin is likely to result in some degree of insulin resistance. Insulin receptors become less responsive to insulin signaling so high levels of glucose remain in circulation for a longer period of time. High fasting blood glucose is one of the markers used to diagnose diseases of insulin resistance, including prediabetes, type 2 diabetes, and polycystic ovary syndrome. Insulin resistance is also associated with obesity, which is a risk factor in certain cancers, including (but not limited to) cancers of the breast, prostate, and colon. More recently, insulin resistance has also been identified as a risk factor in Alzheimer's disease [10–12].

22.2.4 Anticipated Weight Loss

Weight loss is one of the most widely documented side effects of a ketogenic diet. Obviously, this is not always desirable, especially for individuals who are malnourished, already below a desirable weight, or have health issues (such as bowel disease or advanced cancer) that place them at high risk for sarcopenia or cachexia. Although weight stabilization is often possible, weight gain on a ketogenic diet may be difficult to accomplish unless the individual can promote muscle mass accretion through resistance training. There is also speculation that weight gain may interfere with the therapeutic impact of the diet in cancer. Accommodating medical conditions like these underscore the need for trained nutrition and health professionals that can individualize the plan and closely monitor the impact of any nutritional intervention.

22.2.5 Mitochondrial Health [13]

Structurally and functionally healthy mitochondria are essential to maintaining health throughout the lifespan. It is increasingly clear that mitochondrial health for most individuals is determined by more than the genetic code handed down at birth—instead, it is strongly influenced by epigenetic changes, including those related to the type and timing of food intake. Changes in the gut microbiome, in part altered by food choices, can also influence how genes interact with the environment. There is an urgent need to discover new ways to push back against the rising tide of metabolic diseases. Ketogenic metabolic therapy [14] offers great potential here as an adjunct to the current standard of care, even in treatment-resistant diseases, such as glioblastoma multiforme. Moving forward, it is essential that effective prevention strategies incorporate sound nutrition science.

22.3 Glucose and Insulin

Glucose is essential to human life and biology has developed a plethora of mechanisms to facilitate the movement of glucose from the bloodstream into cells. Once inside the cytoplasm of the cell, each glucose molecule is split into two molecules of pyruvate in a process known as glycolysis. In normal cells, most of the pyruvate then crosses the mitochondrial membrane where it is oxidized to generate energy within the Krebs cycle and electron transport chain. Glycolysis also converts nicotinamide adenine dinucleotide (NAD) to its reduced form, NADH, a coenzyme needed to facilitate mitochondrial activities.

When blood glucose levels rise, beta cells in the pancreas secrete insulin, which in turn facilitates the movement of glucose across cell membranes through membrane-embedded protein transporters. Interestingly, changes at the cellular level, including alterations in genetic expression, can alter the number of embedded glucose transporters as well as the amount of glucose that is oxidized relative to the amount that is fermented. Most of these transporters are insulin-independent, though some of their signaling may be activated through insulin-sensing pathways. Glucose transporter 1 (GLUT1), present in most cells and highly expressed in glucose-hungry erythrocytes and endothelial cells of the blood–brain barrier, allows insulin-independent facilitated diffusion across cell membranes based on the concentration gradient. Glucose transporter 2 (GLUT2) is highly expressed in hepatic tissue as well as intestine, kidney, and pancreatic islet beta cells, where it acts as a glucose sensor to stimulate insulin secretion. It is also expressed in neurons and astrocytes. Glucose transporter 3 (GLUT3), another insulin-independent transporter, is essential to the movement of glucose into neurons [15].

The presence of insulin, sensed through insulin receptors embedded in cell membranes, also stimulates the translocation of glucose transporter 4 (GLUT4) from cellular vesicles within the cytoplasm to the surface of the cell, which in turn facilitates the movement of glucose across the cell membrane. GLUT4 is highly concentrated in muscle, cardiac, and adipose tissue, allowing for rapid uptake of glucose. However, persistently high levels of circulating insulin are known to contribute to insulin resistance of these tissues. Exercise can improve insulin sensitivity and transport of glucose through cell membranes thus reducing the amount of insulin needed. Glucose transporter 5 (GLUT5) is specific to fructose rather than glucose and is active in skeletal muscle [16].

Insulin is essential to human life [17]. Individuals who experience acute destruction of pancreatic beta cells, through an autoimmune reaction or potentially through certain enteroviral infections, lose the ability to produce insulin and quickly progress to type 1 diabetes (formerly referred to as "juvenile-onset diabetes"). Before Frederick Banting's discovery of insulin in the 1920s, type 1 diabetes was inevitably fatal. In contrast, type 2 diabetes is most often characterized by prolonged high levels of circulating glucose and insulin due to insulin resistance, primarily in muscle, adipose, and liver tissue. This inability to move glucose into cells stimulates secretion of glucagon (insulin's counterregulatory hormone) from alpha cells in the pancreas. Glucagon has several actions, including mobilization of glycogen (glycogenolysis), further compounding the problems associated with high blood glucose levels. In type 2 diabetes, beta cell function can also deteriorate over time as a result of a disease process that allows amyloid plaques to accumulate in pancreatic islets.

Damage to cellular structure and metabolic function results in further dysregulation of regulatory and counterregulatory hormones that impact metabolism including (but not limited to) glucose homeostasis, fatty acid oxidation, and ketogenesis. Although the mechanisms for these degenerative changes are multifactorial, the expression of these genes can be altered by lifestyle changes that serve to improve insulin sensitivity, such as physical activity. It is now increasingly evident that the adoption of very-low-carbohydrate dietary patterns can also improve insulin sensitivity and glucose homeostasis while significantly reducing the need for drugs and insulin.

Insulin also plays a role in cellular signaling though this is complex and still poorly understood. That said, it is well-documented [18] that high carbohydrate intake and the associated rise in insulin initiates lipogenesis in liver and adipose tissue. These newly synthesized fatty acids are then converted into triglycerides for transport and storage. Upregulation of this activity is known to contribute to a number of metabolic diseases [19], including obesity, hepatic steatosis, diabetes, cardiovascular diseases, and the cluster of symptoms comprising metabolic syndrome.

22.4 Ketogenesis

Ketogenesis involves the biosynthesis of small energy molecules that can then be utilized alongside (or in place of) glucose, fatty acids, and amino acids. Ketogenesis is a normal and natural adaptation that ensures a continuous supply of metabolic fuels during periods of limited food availability or

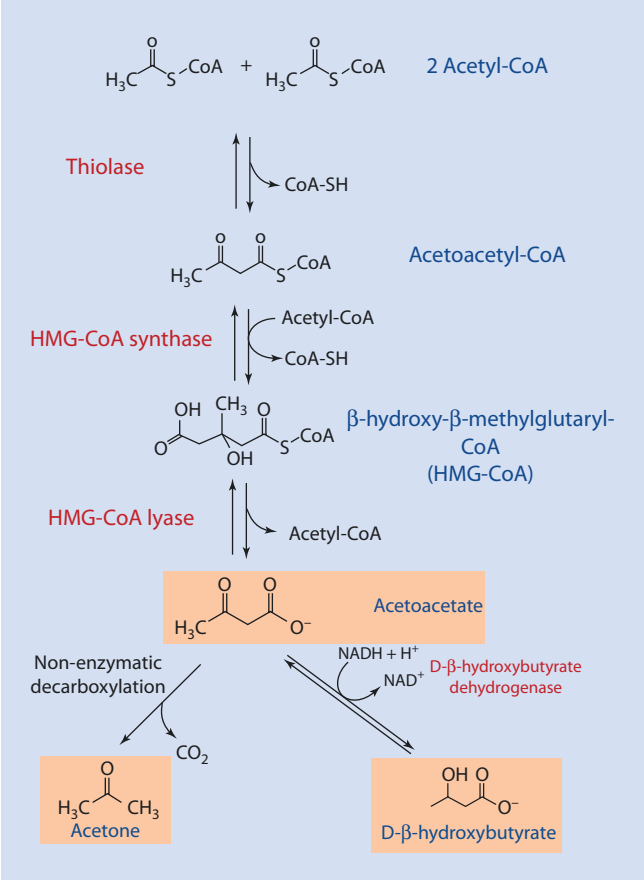

Fig. 22.1 Ketogenesis pathway [21]. The three ketone bodies (acetoacetate, acetone, and beta-hydroxy-butyrate) are marked within an orange box. (Reprinted with permission from ► https://en.wikipedia.org/wiki/File:Ketogenesis.svg)

even frank starvation. However, the metabolic shift to ketosis is also possible in a well-fed state that limits carbohydrate intake. The shift from a standard diet begins with either a short fast or a rigorous restriction in carbohydrate intake. The change in energy substrates from "glucocentric" to "adipocentric" involves a series of predictable metabolic changes that accompany the adoption of a ketogenic dietary pattern [20] (◘ Fig. 22.1).

22.4.1 Step One [20]

Carbohydrate restriction results in a drop in blood glucose levels which in turn reduces insulin secretion. Low glucose levels also stimulate the secretion of the hormone, glucagon, which stimulates glycogenolysis; specifically, the breakdown of glucose stored in the liver as glycogen which in turn liberates approximately 100 g (400 calories) of stored glucose. Glucose is also stored as glycogen in muscle tissue. Muscle glycogen consists of an additional 400–500 g of glucose (1600–2000 calories) but it can only be utilized by the muscle tissue in which it is stored. In essence, muscle glycogen serves as reserve fuel for muscle which is crucial during activities that require a burst of energy, such as sprinting.

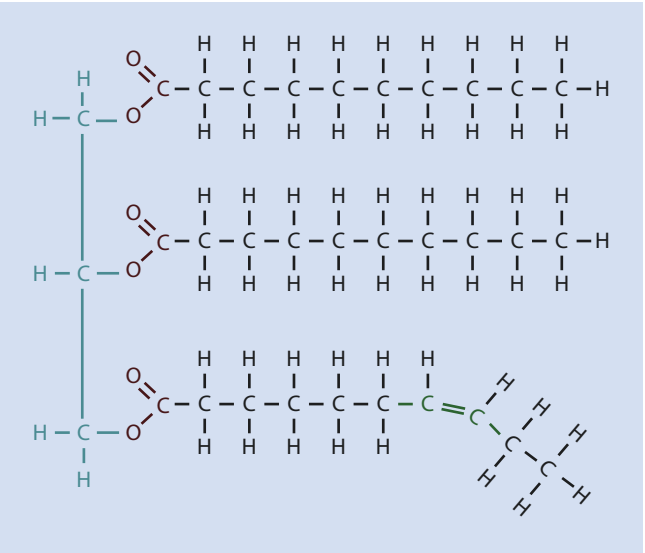

Fig. 22.2 Schematic of triglyceride ester. (Reprinted from Bayly [22]. With permission from Elsevier)

22.4.2 Step Two [20]

Depletion of liver glycogen stores, typically within 18–24 hours, upregulates gluconeogenic activity, primarily in hepatocytes but also in renal cortex. This endogenous production of glucose replaces dietary intake as the major contributor to blood glucose during periods of starvation or low carbohydrate intake. During the transition, low blood glucose levels also stimulate the production of steroid hormones (primarily adrenaline and norepinephrine) which stimulate an increase in gluconeogenic activity, thereby restoring glucose levels to physiological norms. Starvation and fasting are potent initiators but on a smaller scale, gluconeogenesis occurs many times throughout the day and during the overnight fast, effectively maintaining glucose homeostasis. Depending on availability at any given time, lactate, amino acids, and the glycerol backbones from triglycerides can all be used in the endogenous production of glucose.

22.4.2.1 Simple Schematic of a Triglyceride Ester (◘ Fig. 22.2)

A Closer Look at Gluconeogenesis

Most textbook descriptions of the shift to ketosis point to muscle mass degradation as the main source of the amino acids used in gluconeogenesis during fasting or starvation. The amount of degradation has been quantified and, in total starvation, an estimate can predict how long an individual can survive based solely on body fat stores. However, muscle mass degradation does not continue at that same unsustainable rate when dietary intake of fats and protein replace carbohydrates in a ketogenic fed state. In fact, the science suggests that ketone bodies spare both glucose and protein [23]. Fol-

lowing a few days of carbohydrate restriction, gluconeogenesis shifts away from reliance on amino acids obtained from muscle and instead uses the abundant supply of glycerol backbones stripped from triglycerides (described in step 3 of this shift to ketosis). Limiting the discussion to fasting or starvation points to a poor understanding of the adaptations that occur in a very-low-carbohydrate (ketogenic) fed state.

22.4.3 Step Three

By itself, gluconeogenic activity cannot continue to meet the energy needs of the system as this would be dependent on the unsustainable breakdown of lean body tissue. With continued low carbohydrate intake, even in a fed state, fatty acid oxidation is upregulated, flipping the metabolic switch to reliance on energy stored as triglycerides in adipose tissue or provided through diet.

Lipases strip the backbone from triglycerides, releasing free fatty acids into the bloodstream where they are carried throughout most of the body. Exception: most long-chain fatty acids cannot cross the blood–brain barrier (BBB). In a resting state [24], heart and skeletal muscle prefer fatty acids over glucose: "Unlike skeletal muscle, heart muscle functions almost exclusively aerobically, as evidenced by the density of mitochondria in heart muscle. Moreover, the heart has virtually no glycogen reserves. Fatty acids are the heart's main source of fuel, although ketone bodies as well as lactate can serve as fuel for heart muscle. In fact, heart muscle consumes acetoacetate in preference to glucose." All but the most compromised individuals maintain fat stores that are adequate enough to survive for weeks or months during periods of total starvation [25, 26]. Glycerol released in this process is diverted to the liver and renal cortex where it is used primarily as a substrate for gluconeogenesis.

Analogy to a Hybrid Engine

It is easy to lose sight of the fact that humans have historically experienced frequent disruptions in food supply. In modern times and in affluent nations that shortfall has been reduced to a narrow window of time, usually limited to a few hours between meals or overnight.

"Hybrid engine" is often used as a metaphor in describing the flexibility of evolutionary adaptations that ensure utilization of energy reserves. Normal cells and tissue function like tiny hybrid engines maintaining the metabolic flexibility that allows for a seamless integration of fuels from a variety of sources. In that context, it makes sense that a shortage of dietary carbohydrate would require both the endogenous production of new glucose and the breakdown of stored fats into free fatty acids and ketone bodies. (Accumulated mutations in cancer cells render them less metabolically flexible [27]; for example, many cancer cells are unable to upregulate production of key ketolytic enzymes, one of the characteristics that allow them to be targeted through a change in diet.)

22.4.4 Step Four

There are limitations in the utilization of longer chain fatty acids as a source of metabolic fuel for the brain and central nervous system: that is, they cannot cross the BBB, the semipermeable protective interface of highly specialized endothelial cells with uniquely tight junctions that line the blood vessels leading to the brain. Fatty acids also cannot be utilized by cells that lack mitochondria, such as mature red blood cells and lens tissue. For most other tissue, an evolutionary adaptation fills the energy gap through the conversion of fatty acids to ketone bodies [28]; small water-soluble energy molecules that are biosynthesized primarily in hepatocytes and, to a lesser degree, the renal cortex. Certain amino acids can also be converted to ketone bodies. These include L-lysine and L-leucine, which are exclusively ketogenic, along with five others that are conditionally ketogenic.

Ketone bodies are preferentially taken up by heart and muscle tissue but even more important, they readily cross the BBB, serving as the only metabolic fuel other than glucose that can meet the high energy needs of normal brain and central nervous system tissue [29]. This shift to adipocentric fuels plays a critical role in mitochondrial energy metabolism by reducing the demand for both glucose and protein during periods of fasting, starvation, or very low carbohydrate intake.

Is Ketosis Safe?

The level of ketosis achieved through adherence to a therapeutic ketogenic diet represents a normal and desirable adaptation to low availability of dietary carbohydrates. In contrast, dangerously high blood levels of ketone bodies seen in diabetic and alcoholic ketoacidosis are the result of a metabolic derangement that is not associated with the change in diet. Differential characteristics are described in the section on side effects.

Mitochondria in hepatocytes lack the enzyme needed to utilize ketone bodies [30]; therefore, virtually all of the ketones produced there are exported into the bloodstream for distribution throughout the body. As ketone bodies enter circulation, they are immediately taken up and utilized for energy by most normal cells that contain mitochondria. Most importantly, due to their size and solubility, ketone bodies readily cross the BBB, providing up to two-thirds [31] of the brain's ongoing energy needs. This represents roughly 20% of the body's total energy needs. In a ketogenic diet, endogenous ketone production relies on dietary intake of fats as well

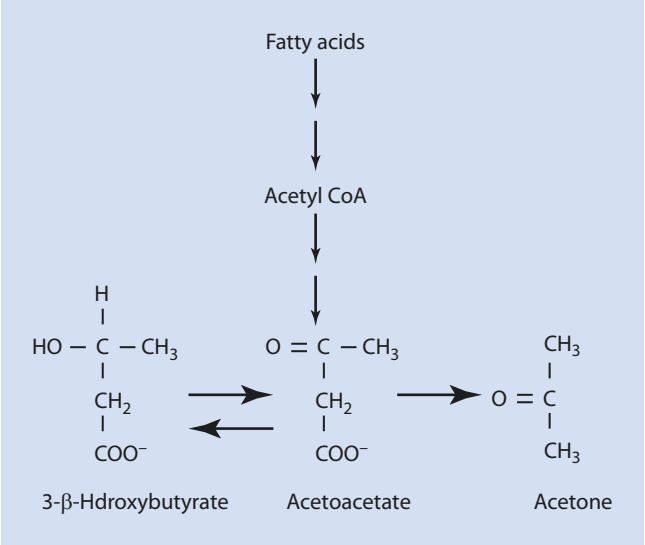

Fig. 22.3 Ketone bodies. (Reprinted from Laffel [31]. With permission from John Wiley & Sons, Inc.)

as robust lipolysis of triglycerides stored in adipose tissue. There are three types of ketone bodies [31]:

- *Acetoacetate* is preferentially taken up by muscle tissue and oxidized as energy. The brain also uses acetoacetate for energy [32, 33]. With keto-adaptation, most acetoacetate is converted (reduced) to D-beta-hydroxybutyrate, primarily by liver and muscle tissue, and returned to circulation.
- *D-beta-hydroxybutyrate* (D-βHB) is initially produced in almost equal proportions as acetoacetate. As the body adapts to ketosis, interconversion of acetoacetate favors the production of D-βHB, a preferred fuel for heart, muscle, and brain tissue.
- *Acetone* is usually produced from the spontaneous breakdown of acetoacetate. Only a small amount of acetone undergoes reactions that allow it to be used for energy. Most of it is simply eliminated from the body as fruity smelling "keto breath" (Fig. 22.3).

Nutritional ketosis is defined as a metabolic state in which beta-hydroxybutyrate (βHB) is present in the blood at a level between 0.5 and 5.0 mmol/L [29, 34]. This represents the body's normal physiological response to a very-low-carbohydrate diet. If levels drop below this threshold, people are no longer in a ketogenic state. Levels above 5.0 mmol/L are not usually seen in adults on standard diets except during fasting, intense exercise, or with exogenous ketone supplementation.

22.4.5 Ketogenic Metabolic Pathway

Adaptation to starvation, fasting, or a diet very low in carbohydrates involves the upregulation of activity in the ketogenic metabolic pathway in order to meet the specific energy needs of tissues and organs. Conventional nutrition textbooks include information on ketone metabolism but it is most often presented as a temporary state with the sole purpose of providing energy during periods of starvation. Another limitation of such descriptions is that they typically blur the distinction between the *physiologically normal* levels of ketones that result from intentional dietary manipulation and the *pathologically high* levels of ketones seen in aberrant metabolic conditions such as alcoholic or diabetic ketoacidosis [7]. This does not acknowledge the unique nature of the ketogenic pathway: that is, as a stunningly sophisticated adaptation not only to periods of prolonged fasting or frank starvation but also to the voluntary restriction of carbohydrate intake that is adopted as part of a ketogenic diet or other very-low-carbohydrate pattern [7].

Utilization of newly synthesized ketone bodies begins as soon as they enter the bloodstream. Beta-hydroxybutyrate and acetoacetate pass from the bloodstream into the cytoplasm of cells via monocarboxylate transporters. These same transporters also allow passage of pyruvate and lactate (which are also monocarboxylates). From the cytoplasm, ketone bodies then pass through the mitochondrial membranes where they are oxidized for energy [29, 35], generating less reactive oxygen species (ROS) than either glucose or fatty acid metabolism. Next, a sustained rise in serum ketone levels drives the upregulation of ketolytic enzymes which serve to oxidize ketone bodies within the mitochondria of normally functioning cells.

In a standard diet, carbohydrate intake makes up more than half of total calories, much of that coming from grains, starches, and added sugars. In contrast, a classic ketogenic diet limits carbohydrate to an average of 6% of total calories [36, 37]. With protein kept low (but adequate in meeting the body's needs), the amount of fat in the diet can rise to over 80% of calories [20, 37].

22.5 History of Use in Epilepsy

The ketogenic diet has a century-long history of use as a dietary therapy for intractable epilepsy. By the start of the twenty-first century, it had passed through the clinic trial process, which led to greater acceptance as an evidence-based treatment [36–38]. There is general consensus on the initiation protocol for the classic ketogenic diet and nearly 100 hospitals in the United States [37, 39] alone are staffed with professionals, including neurologists, epileptologists, and registered dietitians that are trained in diet implementation and support. However, significant barriers to resources remain as most of the centers are concentrated in urban areas, leaving large regions of the country, including the states of Alaska and Hawaii, without access to clinical services.

Liberalized forms of the diet have emerged, including:

1. Modified Atkins (no tracking of protein or fats)

Table 22.1 Macronutrients as a percentage of total daily calories in a eucaloric ketogenic diet

	Fat (%)	Protein (%)	Carbohydrate (%)
Standard diet (AMDR)	20–35	10–35	45–65
Ketogenic diet (rigorous to moderate)	78–86	8–12	2–10

Based on data from Ref. [42]
These percentages represent a typical range—individual patterns may vary

2. Modified ketogenic diet (lower ratio of fat to carbohydrate/protein)
3. Low glycemic index diet (includes limited portions of carbohydrates, such as bread and pasta, with a GI index of <50)
4. Medium-chain triglyceride (MCT) oil diet (allows greater portions of vegetables, berries, and protein given that ketosis is enhanced by the inclusion of ketogenic MCT oil) [34, 40]

Although the level of ketosis is not as robust with liberalized versions as it is with the classic ketogenic diet, long-term adherence may be more realistic, especially in adolescents and adults. The ratio of fat grams to carbohydrate/protein grams is lower in modified versions, thus reducing the number of calories needed from fat [41]. Another benefit to liberalized plans is that diet initiation is usually more gradual, reducing the incidence and severity of adverse effects such as nausea, hypoglycemia, or mild metabolic acidosis that are commonly seen in patients who begin the diet with a fast. In fact, most adult patients who opt for less rigorous versions are not routinely hospitalized at initiation which in turn has greater appeal to professionals, families, and insurers (Table 22.1).

As noted, the ketogenic diet has nearly a century of use as a medical dietary therapy. There has recently been a surge in research assessing the downstream metabolic effects of ketosis at both the system and cellular level, and a corresponding surge of interest in widespread implementation of the diet as an adjuvant or stand-alone treatment for a variety of seemingly unrelated diseases. Further progress in exploring the diet's potential will most likely arise from the demand for nutritional therapy from an informed and empowered public.

22.6 Diseases of Insulin Resistance

Recent results from both preclinical and clinical research provide evidence to support prior speculation that diseases of insulin resistance can be successfully treated using ketogenic diet therapy [43–46]. Despite mounting evidence, the majority of practitioners in the conventional medical and nutrition communities still view ketogenic diets as a fad, often labeling them as "too extreme" or "dangerous."

22.6.1 Obesity

The bias against ketogenic diet therapy in obesity medicine continues despite research showing a clear advantage for low-carbohydrate patterns in weight loss. In a 2007 paper published in the *Journal of the American Medical Association*, a randomized trial known as "The A to Z Weight Loss Study" tested four dietary and lifestyle interventions: Atkins ("induction" at 20 g carbohydrate per day for several months then an "ongoing weight loss" phase at 50 g/day), LEARN (standard guidelines plus lifestyle recommendations), Ornish (10% fat/low-protein/very-high-carbohydrate and primarily plant-based), and Zone (40% carbohydrate/30% protein/30% fat) [44]. At 2 and 6 months, weight loss was significantly greater, and, at the endpoint of 12 months, weight loss was still greatest in the Atkins group. The authors also assessed other biomarkers of health, including those assumed to be negatively impacted by a very-low-carbohydrate diet, and the findings did not confirm this bias:

» Many concerns have been expressed that low-carbohydrate weight-loss diets, high in total and saturated fat, will adversely affect blood lipid levels and cardiovascular risk. These concerns have not been substantiated in recent weight-loss diet trials. The recent trials, like the current study, have consistently reported that triglycerides, HDL-C, blood pressure, and measures of insulin resistance either were not significantly different or were more favorable for the very-low-carbohydrate groups. [44]

Given the rising tide of obesity and an increase in obesity-linked comorbidities, there is an urgent need to act on the evidence that supports a sea change in obesity medicine guidelines and practice. Well-formulated and nutritionally complete ketogenic diets, together with education and support provided by clinicians trained in proper implementation, are essential to moving ketogenic diets forward as the preferred nutritional approach to obesity treatment. This could include private models (i.e., corporate wellness programs) as well as traditional reimbursement schedules through private insurers.

22.6.2 Diabetes

Low carbohydrate and ketogenic diets have experienced a recent resurgence as the preferred dietary pattern for individuals with diabetes. In fact, the evidence from decades of research is so strong that it has prompted a group of obesity medicine researchers and clinicians to unequivocally support "the use of low-carbohydrate diets as the first approach to treating type 2 diabetes and as the most effective adjunct to pharmacology in type 1," even taking this a step further to state that "the burden of proof rests with those who are opposed" [45].

Results of a 10-week interventional trial aimed at reducing hemoglobin A1c level, medication use, and weight in individuals with type 2 diabetes [46]. In this study, researchers com-

pared an onsite program with remote means using an online platform to deliver a comprehensive intervention that included a ketogenic diet, behavioral counseling, digital coaching, and physician-guided medication management. Results from both groups (totaling 238 participants) who completed the study included a 1% reduction from baseline in HbA1c, mean body mass reduction of 7.2%, and a reduction in the number and/or dosage of diabetes medications in the majority of participants. What is intriguing here is that these results support the development of medically supervised programs that utilize digital coaching to expand the implementation of ketogenic diet therapy beyond the geographical limitations imposed by reliance on traditional brick-and-mortar clinics.

22.6.3 Polycystic Ovary Syndrome

Potential therapeutic applications of ketogenic diets include polycystic ovary syndrome (PCOS). This is understandable given the high prevalence of insulin resistance in this population (65–70% of all women with PCOS, rising to 70–80% of obese women with this disease). The authors of a review in the *European Journal of Clinical Nutrition* stated that "although we have only preliminary evidence…there are clear mechanisms that are consistent with the physiological plausibility of such dietary therapy" [47]. The preliminary evidence referred to in this review included results of a pilot study of five obese or overweight women with PCOS who completed a 6-month trial of a low-carbohydrate (20 g/day) ketogenic diet. When compared to baseline, there was a 54% reduction in fasting insulin levels [48] with improvements in other markers of the disease as well. (Of note, two of the women became pregnant during this study despite a prior history of infertility.)

22.7 Cancer

There is mounting preclinical evidence to support the use of a ketogenic diet as an adjunct in cancer treatment [49–51]. Clinical trials are currently investigating the effects of combining diet therapy with standard of care. Unfortunately, most of these clinical studies are underpowered and poorly funded.

22.7.1 Cancer Cells Are Reliant on Fermentable Fuels

In 2005, biologist Dr. Thomas Seyfried and his colleague Dr. Purna Mukherjee were leaders in reexamining a characteristic of most cancer cells: That is, to produce energy, they preferentially ferment glucose in the cell's cytoplasm even when there is sufficient oxygen to support energy generation using the more efficient mitochondrial pathway. This particular characteristic of cancer is known as the "Warburg effect" [49], named after German biochemist and Nobel laureate Otto Warburg.

Dr. Otto Warburg: Nobel Laureate

Otto Warburg was a prominent German biochemist of the early twentieth century with a special interest in the metabolism of cancer cells. His famous observation, now known as the Warburg effect, was that cancer cells increase their rate of glycolysis even in the presence of oxygen. Dr. Seyfried sums it up this way:

Warburg's theory was based on his findings that all cancer cells have some defect in their ability to use oxygen to obtain energy through mitochondrial respiration. As a result, cancer cells relied more on fermentation than on respiration to obtain energy in order to compensate for their defective respiration. The reliance on fermentation even in the presence of sufficient oxygen was referred to as the Warburg effect. [50]

In a review published in the journal *Nutrition and Metabolism*, Seyfried and Mukherjee presented a strong case in support of Warburg's central theory that cancer is the downstream effect of damage to mitochondria [51]. They also describe the mechanism by which ROS from damaged respiration could produce mutations in the nucleus. Put simply, inefficiencies in cellular energy metabolism can be compensated for by an increase in glucose fermentation and, if left unchecked, ultimately transforms a normal cell into a cancer cell [51]. This line of reasoning suggests that cancer is primarily a mitochondrial metabolic disease that can be targeted with therapies, including ketogenic diet, that exploit this vulnerability. At the same time, Seyfried and Mukherjee also reiterated a fact well-known in cancer research and practice: namely, that the amino acid glutamine is another primary source of fuel that drives cancer progression.

Fermentation is a primitive process that meets bacteria's simple needs for energy. In humans, fermentation by itself usually contributes relatively little to overall energy production. That said, all cells ferment a small percentage of pyruvate, but the rate of glycolysis in cancer cells is typically 10–15 times the rate in a normal cell [52]. For this switch in the fate of glucose to occur, cells must also upregulate activities that allow more glucose to enter the cancer cell. This is accomplished through an increase in the number of glucose transporters and insulin receptors on the cell's surface. Fermentation produces lactic acid which, in large amounts, is toxic to cells, so there are mechanisms in place in all cells to quickly shunt lactic acid to the microenvironment. This increased acidity in the microenvironment of cancer cells increases inflammation, which in turn facilitates both local progression and metastatic spread of the disease. Fermentation also results in many more ROS molecules which inflict further damage to already dysfunctional mitochondria leading to even more cellular disruption and disease progression. This effect of ROS is not specific to cancer but instead is relevant in a wide array of other chronic and degenerative conditions.

Ketogenic diets also dampen spikes in glucose [53]. This not only reduces insulin levels but also lowers levels of an associated hormone, insulin-like growth factor 1 (IGF-1). IGF-1 and its cell receptor, IGF-1R, are upregulated in cancer and both can drive disease progression. In fact, activity in this pathway can be two to three times greater than in normal cells, making IGF-1 a target of many cancer drugs. Ketogenic diets that are calculated to meet but not exceed protein requirements may influence epigenetic changes that lead to the downregulation of activity in the mTOR pathway [54, 55]. This is significant given that upregulated mTOR in cancer is associated with disease progression (Figs. 22.4 and 22.5).

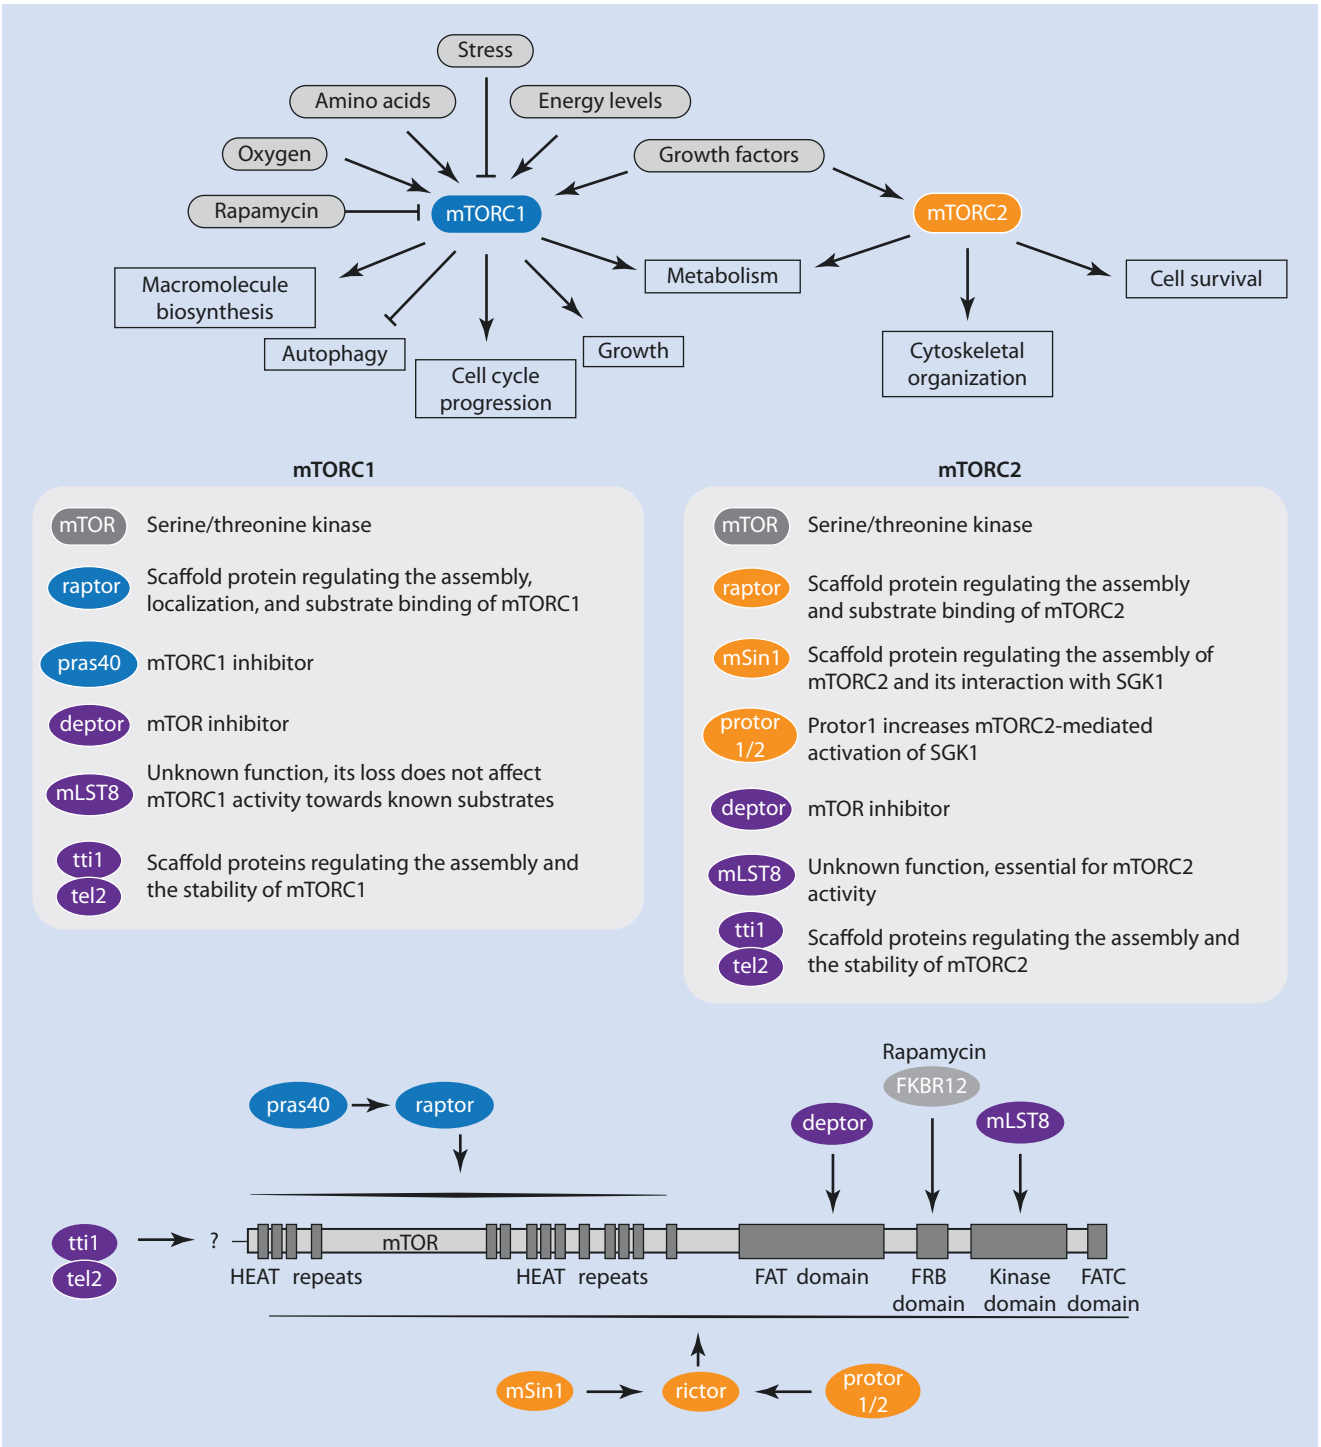

Fig. 22.4 mTOR signaling in growth control and disease. (Reprinted from Laplante and Sabatini [55]. With permission from Elsevier)

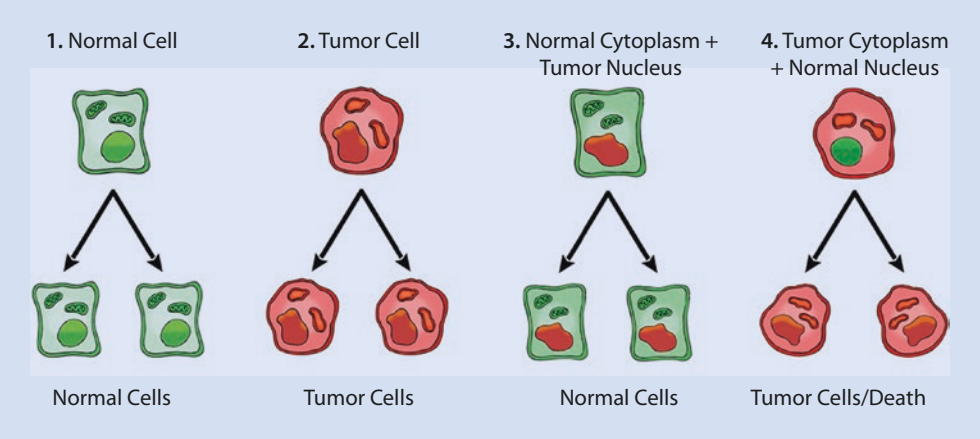

Fig. 22.5 Cybrid diagram [56]. (Courtesy of Jeffrey Ling and Thomas N. Seyfried)

Cancer as a Mitochondrial Metabolic Disease

Dr. Thomas Seyfried and colleagues describes some intriguing research involving nuclear cytoplasm transfer experiments in a paper entitled *Cancer as a mitochondrial metabolic disease* published in *Frontiers in Cell and Developmental Biology* and in *Cancer as a Metabolic Disease* [56, 57]. In nuclear transfer experiments, cytoplasmic hybrid cells (cybrids) were created by transferring *tumor* nuclei into cells with *normal* cytoplasm. The result was cells that replicated and survived, despite having a nucleus with mutated DNA. Other cybrids were created by transferring *normal* nuclei into tumor cells containing *cytoplasm that displayed the Warburg effect*. These cells also replicated but the majority did not survive. According to Dr. Seyfried: "The results suggest that nuclear genomic defects alone cannot account for the origin of tumors, and that normal mitochondria can suppress tumorigenesis. In essence, the evidence is consistent with the theory that cancer is primarily a mitochondrial metabolic disease." [56].

22.8 Neurodegenerative Diseases

Ketone bodies, particularly beta-hydroxybutyrate and acetoacetate, are a preferred energy metabolite for much of the brain and central nervous system, and a large body of evidence combined with a century-long history of use have consistently demonstrated neuroprotective and neurotherapeutic benefits of ketogenic diets in epilepsy [58]. Preliminary research indicates that these benefits may extend to applications in other neurological diseases and disorders, including autism spectrum disorder, traumatic brain injury, spinal cord injury, mood disorders, and even migraines. Several of these studies are included in a book edited by Susan Masino, PhD [59].

The Masino book also highlights and expands on earlier research pointing to therapeutic benefit of ketogenic therapies for neurodegenerative diseases, including amyotrophic lateral sclerosis [59, 60], Parkinson's disease [61], Alzheimer's disease [62], and mild cognitive impairment [62]. It is important to note that existing drug therapies offer only modest and temporary benefit in slowing disease progression and there is no curative therapy for any of these devastating diseases.

Recently, another mechanism underlying improved cognition has been elucidated by research, that is, the understanding that a ketogenic diet and/or ketone supplementation spares NAD+ (the oxidized form of NAD) [63, 64]. This is significant given that cell senescence and degeneration is associated with a decrease in the NAD+ pool, which in turn epigenetically impacts downstream cell signaling, particularly in activities related to SIRT1.

RECHARGE: Mild Cognitive Impairment and Alzheimer's Disease

Alzheimer's disease is characterized as a disorder of impaired cerebral glucose metabolism. Ironically and very tragically, the drug most commonly prescribed to treat this disease targets that deficiency by making *even more* glucose available to neurons. Instead, it makes sense to investigate ways to reduce reliance on glucose as the primary fuel by replacing glucose with ketone bodies. Ketone bodies are preferentially taken up and readily metabolized by most normal brain tissue and there is a large body of evidence that clearly demonstrates neuroprotective and neurotherapeutic properties. This could amount to a win/win/win in Alzheimer's disease [64, 65].

The MEND trial investigated the effects of changes in diet and lifestyle on symptoms of mild cognitive impairment and early Alzheimer's in a small group of older adults [65]. Interventions included (but were not

limited to) lowering the intake of grains and refined starches, adding MCT and coconut oil, optimizing sleep, practicing daily intermittent fasting, and reducing stress through mind/body practices. Subjects could pick and choose from a smorgasbord of these options that as single therapies would have little total impact on disease but taken together improved outcomes for a majority of participants. This emphasis on individualizing protocols has recently been rebranded as the Bredesen Protocol™ [63, 65].

Combination therapies rather than miracle drug single agents have proven to be the solution for long-term management of other diseases, most notably HIV-AIDS. It is worthy to note that the development of that successful protocol was not made within the context of conventional medical model that tests one drug or therapy at a time in clinical trials. In fact, that model had hindered progress but was ultimately overshadowed by a grassroots movement by impassioned researchers, doctors, and the empowered lay people that combined scientific research with political activism.

22.9 Risk/Benefit Analysis

It is essential to conduct a risk/benefit analysis before initiating a ketogenic diet. This includes assessment through an intake that gathers information on the patient's health history, including demographics, present and past diagnoses, interventions, comorbidities, hospitalizations, clinical symptoms, lab results, and medications and supplements. A nutrition intake should include information about current dietary pattern and history of diets for weight loss or health improvement. It should identify conditions that may limit food choices, such as food allergies, intolerances, aversions, FODMAP issues, philosophy, and if applicable, religious dietary laws. Potential impacts of any physical or cognitive limitations, social environment, family responsibilities, financial limitations, cultural influences, and level of support need to be assessed as well.

22.9.1 Baseline Laboratory Evaluation

At a minimum, the following labs should be drawn prior to initiating a diet and the results evaluated alongside other information used in the risk/benefit analysis. Disease-specific biomarkers, such as carcinoembryonic antigen (CEA) in cancer or thyroid autoantibodies (anti-thyroid peroxidase and anti-thyroglobulin) in suspected autoimmune thyroid disease, should also be tested at baseline. Other labs may be ordered by the integrative or functional doctor to test for metabolic issues that may impact implementation or compliance. For example, an organic acids test may identify a pre-existing, yet previously undiagnosed, problem that could result in a debilitating symptom such as fatigue if the underlying disorder is not addressed prior to initiation of a ketogenic diet. Other tests include but are not limited to ferritin, uric acid, urine organic acids (Genova), comprehensive fatty acid profiles (such as the one offered through Mayo Medical Laboratories), and nutrient assessments including selenium, B12, methylmalonic acid, and folate [38].

22.9.2 Blood Panel

- Complete blood count (CBC)
- Comprehensive metabolic panel (CMP)
- Full thyroid panel (including reverse T3)
- 25-hydroxyvitamin D (optimal levels: 50–80 ng/dL)
- Red blood cell (RBC) magnesium
- Selenium
- Vitamin B12, serum
- Methylmalonic acid
- Folate
- Thiamin
- Riboflavin
- Niacin
- Pantothenate
- Biotin
- Glycated hemoglobin (HbA1c)
- Fasting insulin (as a baseline for comparison and to detect hyperinsulinemia)
- Carnitine panel (vegans are at risk of low levels due to the lack of dietary intake of carnitine; individuals experiencing catabolic events may also be low at baseline; high values for acyl/esterified are acceptable in those who are already in ketosis)
- Advanced lipid panel (e.g., NMR) including particle count and particle density
- High sensitivity C-reactive protein (hsCRP)
- Homocysteine (optimal level: low end of the normal range)

Note that the ranges typically used in certain labs, such as 25-hydroxyvitamin D and homocysteine, may not be optimal. Over time, levels of carnitine and insulin may drop below the optimal range, so retesting at intervals is essential to proper monitoring.

22.9.3 Absolute Contraindications

In 2008, a special report was published entitled "Optimal clinical management of children receiving the ketogenic diet: Recommendations of the International Ketogenic Diet Study Group" [38]. The 24 authors identified a set of absolute contraindications to the use of the diet. These should be ruled out during any risk/benefit analysis completed prior to initiating the diet. Absolute contraindications include:

- Carnitine deficiency (primary)
- Carnitine palmitoyltransferase (CPT) I or II deficiency

- Carnitine translocase deficiency
- β-oxidation defects
  - Medium-chain acyl dehydrogenase deficiency (MCAD)
  - Long-chain acyl dehydrogenase deficiency (LCAD)
  - Short-chain acyl dehydrogenase deficiency (SCAD)
  - Long-chain 3-hydroxyacyl-CoA deficiency
  - Medium-chain 3-hydroxyacyl-CoA deficiency.
- Pyruvate carboxylase deficiency
- Porphyria

How Common Are Contraindications?

With the exception of adult-onset porphyria, most of these limiting conditions are identified in childhood [36]. However, secondary carnitine deficiency can develop in individuals due to an increase in the use of carnitine predicated by a ketogenic diet as carnitine is needed to support the activity of the mitochondrial carnitine shuttle. It can also develop as a result of surgeries, serious injuries, or catabolic treatments, such as chemotherapy. Those who follow primarily plant-based diets and those with genetic variants that negatively impact the biosynthesis of carnitine are also at a higher risk of deficiency.

22.9.4 Relative Contraindications

In addition to absolute contraindications, there are a significant number of diseases, conditions, and situations that preclude or complicate initiation and compliance. The functional or integrative team should consider these in the planning process [36–41].

- Conditions that require medical and nutritional monitoring by a skilled integrative team
- Conditions that interfere with the ability to keep glucose low and steady
- Inability to comply with implementation guidelines

Potential side effects also need to be addressed prior to initiating the diet. These can be reduced in number and severity by proactive education and support during the transition. These side effects are discussed in detail in the section on transitioning to the ketogenic diet.

22.10 Macronutrient Calculations

The ketogenic diet specialist aids the integrative or functional medicine team in developing an initial macronutrient prescription. At best, this should be viewed as simply an estimate of where to start. Expect to periodically review and refine this prescription.

22.10.1 Protein Target

Most estimates of protein needs are very broad and inclusive. The Recommended Dietary Allowance for protein stands at 0.8 g of protein per kilogram of body weight, an intake that the Food and Nutrition Board of the Institute of Medicine has determined as adequate for over 97% of healthy Americans [66]. However, there are other considerations, including: (1) this amount was determined by studies of people following a standard diet, (2) this recommendation is based on *actual* body weight instead of *ideal* weight, and (3) protein needs are higher in subsets of the population including athletes and the elderly, as well as individuals who are undergoing cancer treatment or recovering from surgery. Women who are pregnant or lactating need to follow the medical and nutrition advice of their gynecologist. Aside from these exceptions, patients following ketogenic diets may need to adjust protein intake to support tissue repair and maintenance or to maintain muscle mass but there are simply too many variables here to come up with a single recommendation that can be generalized to everyone in ketosis.

Variables to Consider in Setting a Protein Target

- Older adults may benefit from more protein as greater intake is associated with reduced mortality, but this may simply reflect confounders that impact nutrient intake and digestion rather than an increased need for protein.
- Those who engage in moderate or vigorous activity may benefit from a slight increase in protein intake, especially in the form of branched-chain amino acids before or during the activity. The needs of elite athletes should be calculated by a nutritionist that specializes in low carbohydrate nutrition for this special population.
- Excess protein is converted to glucose via gluconeogenesis. This can interfere with ketosis.
- Excess protein stimulates mTOR and IGF-1 activity which may be detrimental in individuals with cancer [54, 55].
- Glutamine is fermented for energy in the mitochondria of many types of cancer cells.
- A single high-protein meal can stimulate an insulin response sufficient to suppress ketogenesis. This is especially evident with dairy and egg protein.
- The RDA for protein for a 5′9″ individual weighing 220 lbs. (100 kg) is 80 g and the RDA for a 5′9″ individual weighing an ideal 154 lbs. (70 kg) is 56 g. *Where is the evidence* that a heavier person needs an additional 24 g of protein to support what is basically the same lean body mass? Some may argue that more protein is needed to maintain the muscle tissue needed to support the extra weight, but realistically, the extra amount of protein—if needed at all—is likely to be very small, perhaps a few extra grams per day.

22.10.2 Carbohydrate

Determining carbohydrate intake does not entail a calculation as there is no requirement for dietary intake. Instead, the limit is based on an individual's response to carbohydrate intake [47]. Most people are able to maintain nutritional ketosis with carbohydrate intake between 20 and 50 net grams. Adopting a target at the lower end of the range may help to facilitate adaptation to the diet, particularly in the early days and weeks.

Patients following the ketogenic diet should be counseled to eliminate non-foods like coffee creamers that contain processed fats and to focus instead on consuming nutrient-dense non-starchy vegetables, nuts, and seeds that are high in fat and fiber. Consider these factors in setting carbohydrate limits:

- The most rigorous ketogenic diets (i.e.. for epilepsy or cancer) generally limit net carbohydrates (total carbohydrates minus fiber) to 12–16 g per day.
- Patients with thyroid disease or other hormone imbalances may be more successful and feel better during the transition if the carbohydrate limit is set at 20–25 g.
- Patients recovering from surgery, or those currently receiving chemotherapy or radiation, may benefit from a higher carbohydrate intake (20–40 g) to allow for a more liberal intake of nutrient dense foods.
- A more liberal intake of salad or sauté greens is not likely to interfere with ketosis, especially when consumed with oil-based sugar-free dressings.

22.10.3 Fats

While protein targets and carbohydrate limits are likely to remain stable over the early weeks and months of the diet, the amount of fat needed will increase or decrease in response to overall energy needs [38, 42, 47]. As stated earlier, the initial macronutrient prescription is only an estimate based on patient demographics, level of physical activity, and accommodations needed during active treatment of specific disease such as cancer or diabetes. The amount and/or type of fat initially prescribed may also reflect initial patient tolerance to an intake that may be roughly two-and-a-half times that of the baseline pattern. Variation in intake is amplified in those with high energy needs as they may require up to 300 g of fat per day to maintain current weight (if that is a goal). Comorbidities such as gallbladder disease may also impact digestion and tolerance and should be addressed proactively.

Patient education should include information on which fats and oils to include in the diet and which to eliminate. Patients may also need guidance on how to incorporate fats and oils into meals and snacks.

Dairy fats have traditionally played a large role in ketogenic diets for children. However, many functional and integrative practitioners may suggest a dairy-free diet for their dairy-sensitive patients, and this will require even more intensive support from the nutritionist. There is also some concern over estrogen metabolites in dairy, particularly for those with hormone-sensitive cancers.

Key Points

- Most protein- and fat-rich animal and plant foods contain a complex blend of fats and oils with varying amounts of saturated and unsaturated fatty acid chains
- The ratio of omega-6 to omega-3 intake appears to influence systemic inflammation: High ratios seen in most standard diets (i.e., 15:1) are assumed to be pro-inflammatory [57]
- A subset of fatty acids referred to as essential fatty acids (EFAs) cannot be biosynthesized efficiently in humans and need to be included in the diet.

Table 22.2; Please see ▶ Chap. 10.

22.10.4 The Question of Calorie Restriction

The benefits of a calorie-restricted ketogenic diet include (1) intentional weight loss, (2) lower blood glucose and insulin, (3) more rapid transition to ketosis, (4) improved mitochondrial health, and (4) greater initial impact on disease-promoting pathways, such as angiogenesis, mTOR, and IGF-1 in cancer. That said, it is crucial to ensure that caloric restriction does not provoke or worsen malnutrition. All factors that impact GI functions must be evaluated and addressed prior to setting the diet prescription.

Weight loss is almost always present in the early days and weeks of the diet as the switch involves removing approximately half of total calories previously consumed as carbohydrate-containing food. Most patients adapt slowly to this change; in effect, they may inadvertently restrict calories. The integrative or functional team needs to assess baseline body fat percentage and lean body mass (via BIA, BodPod, DEXA/DXA, calipers) then carefully monitor weight loss to ensure that it is healthy and sustainable. Inadvertent weight loss is especially problematic in those who need to maintain or even gain weight during this transition so once again, proactive measures need to be in place before the transition to a ketogenic diet. Variations in approach to initiating the diet will be discussed in the following section.

It is important to note that many of the same benefits of caloric restriction can be achieved—often without weight loss—through the use of a fasting regimen. One of the simplest to initiate and maintain is daily intermittent fasting (referred to now as "time-restricted eating"). This is easily accomplished by avoiding all food for 3–4 hours prior to bedtime and refraining from carbohydrate- or protein-containing foods for the first few hours after awakening. Limited amounts of fats, such as MCT oil and/or ghee, are often consumed in a morning beverage to help extend the modified fast to 14–16 hours. This facilitates autophagy while also increasing morning ketone levels and simultaneously keeping glucose low and steady.

Table 22.2 Table of fats and oils

Sources	Choose most often	Limited amounts	Eliminate
Omega-3 (rich in EPA, DHA, ALA)			
Animal	Wild-caught cold-water fish including sardines, mackerel, salmon, and trout (rich in EPA/DHA)	Fish high up in the food chain (high concentrations of heavy metals and low in EPA/DHA) tuna, swordfish, halibut	Farmed fish with heavy contamination including tilapia, salmon, trout
Plant	Flaxseed, chia seed, hemp, walnut	Flaxseed oil (easily oxidized)	GMO flaxseed (due to crop handling practices)
Omega- 6 (rich in LA, GLA)			
Animal	Fresh or frozen grass-fed pastured proteins/fats including beef, lamb, pork, poultry, dairy, properly sourced crustaceans	Processed animal products including deli meats (even from grass-fed and pastured sources)	Fresh/frozen/processed CAFO beef, pork, poultry, eggs or questionably sourced crustaceans
Plant	Small amounts of GLA-rich oils including borage, black currant, evening primrose	Oils including cold pressed non-GMO sunflower, sesame, canola	Soybean, corn, and all other GMO heat-damaged, solvent refined oils
Other mono- and polyunsaturated oils			
Animal	Animal fat from responsibly raised animals and fish oil from wild-caught (preferably) cold water fish and shellfish	n/a	Fats and oils from animals and fish/shellfish coming from CAFOs, fish farms, and contaminated fisheries
Plant	Nuts and seeds; oils including cold-pressed and minimally refined olive and avocado	Brazil nuts (concerns over radium and excess selenium)	Hydrogenated lard
Medium-chain triglyceride oils (uniquely ketogenic)			
Animal	Dairy fats from goats (when available)	n/a	n/a
Plant	Coconut and palm oil (including red palm oil)	n/a	Hydrogenated coconut and palm oils
Saturated fats (most often some combination of saturated and unsaturated fats)			
Animal	Animal and dairy fats from responsibly raised animals	Caveat for individuals with hormone-sensitive cancers: dairy products contain estrogen metabolites	Processed and packaged products containing fats, starches, and sugars
Plant	See medium-chain triglycerides		Same as above
Trans fats			
Animal	Small amounts naturally occurring in meat and dairy	n/a	Hydrogenated animal fats including commercial lard
Plant	n/a	n/a	Hydrogenated margarine and oils (mostly found in processed foods)

Based on data from Ref. [66]
EPA eicosapentaenoic acid (omega-3), *DHA* docosahexaenoic acid (omega-3), *ALA* alpha-linolenic acid (omega-3), *LA* linoleic acid (omega-6), *GLA* gamma-linolenic acid (omega-6), *AA* Arachidonic acid (omega-6), *CAFO* Concentrated animal feeding operation

22.10.5 Food Trackers and Meal Planners

Trackers and planners are important tools to both practitioners and clients/patients. When used properly, accountability for food choices is visible, which can help with compliance. There has been a rapid rise in the number and quality of food tracking apps and patients should be encouraged to use some method of recording intake (though some will still prefer to use written food logs). Used properly, trackers can provide direct feedback to the client/patient that they can then use to refine the plan. For example, Cronometer displays details on essential amino acids, comparing actual intake to the RDA. At a glance, clients/patients can see if they are meeting that requirement. Meal planning tools are not as readily available as trackers. Currently, the best and most accurate ketogenic meal planner is the KetoDietCalculator developed and maintained by The Charlie Foundation [39]. Although this is an important tool for dietitians and nutritionists who work with children, it is not used as frequently with adults given the additional steps needed to access it and the steep

learning curve needed to work with this program. Accessing a patient's food records through one of these tools can help the practitioner spot areas of concern, such as inadvertent non-compliance or a lack of variety in food choices.

22.11 Food and Supplement Recommendations

22.11.1 Eliminate the Following

- *Sugars*

Read ingredient labels carefully. Eliminate agave nectar, honey, molasses, and evaporated cane juice. Many other sugars can be identified by their "-ose" endings (sucrose, dextrose, maltose).

- *Grains*

Eliminate wheat, corn, oats, rye, barley, spelt, triticale, quinoa, and bulgur.

- *Starchy Vegetables*

Eliminate potatoes, sweet potatoes, yams, winter squash, peas, and root vegetables.

- *Starchy or High-Glycemic Fruits*

Eliminate bananas, citrus, pears, grapes, pineapple, and watermelon. (Small amounts of most berries and a slice or two of some fruits can be keto-friendly if carbohydrate content is kept low.)

- *Legumes*

Eliminate peanuts, soy, garbanzos, beans, dried peas, and lentils. (Low glycemic index or vegetarian plans may include legumes.)

- *Milk* – It contains milk sugar (lactose).
- *Eliminate trans fats, heat-extracted and solvent-refined plant oils, and oxidized oils.*
- *Sugar Alcohols*

Eliminate polyol sugar alcohols in foods with ingredients that ends in "-ol" (sorbitol, mannitol, maltitol). These interfere with ketosis. *Exception*: Small amounts of erythritol or xylitol are allowed. (Note that xylitol is toxic to dogs.)

- *Alcohol (during the Transition)*

After keto-adaptation, a single shot of straight spirits or a glass of dry red wine may be well tolerated. Track its effect on ketones.

22.11.2 Allowed Foods

- *Vegetables* (not a complete list):
  - Asparagus
  - Broccoli
  - Brussels sprouts
  - Cabbage
  - Cauliflower
  - Celery
  - Cucumber
  - Kale
  - Mushrooms
  - Salad greens
  - Sauté greens (such as chard, beet greens, mustard greens)
  - Zucchini
- *After keto-adaptation, expand the options:*
  - Eggplant
  - Garlic
  - Onions
  - Peppers
  - Tomatoes
  - Turnips
  - Winter squash
- *Fruits:*
  - Apple (a few very thin slices)
  - Avocados (Hass)
  - Berries (keep it to <2 g of carb per meal)
  - Grapefruit (a few sections)
  - Olives (use more like a condiment)
- *Proteins:*
  - Beef
  - Eggs (preferably from free-range hens)
  - Lamb
  - Pork (including limited amounts of bacon and sausage)
  - Poultry
  - Seafood (wild-caught fish and shellfish)
  - Wild game meats
- *Dairy (limit in hormone-sensitive cancers):*
  - Cheese (hard cheeses, such as cheddar or Parmesan or soft, high-fat cheeses, such as Brie)
  - Full-fat "original" cream cheese
  - Heavy whipping cream
  - Sour cream (cultured, without added starches or fillers)
- *Nuts and seeds:*
  - Almonds (including almond butter, almond flour, almond milk)
  - Brazil nuts (rich in selenium—limit of two per day)
  - Chia seeds
  - Coconut (including unsweetened meat, milk, cream, or flour)
  - Flaxseed (rich in healthy omega-3s and fiber; may not be advisable in some cancers)
  - Hazelnuts
  - Hemp hearts/seeds
  - Macadamias (good choice: high in healthy fat; low in carbs and protein)
  - Pecans
  - Walnuts (good choice: fewer omega-6s than most nuts)

- *Fats and oils:*
  - Lard, tallow, or other saturated animal fats (such as duck fat)
  - Butter or ghee (if including dairy fats in the plan)
  - Buttery spreads (such as Earth Balance or Melt if substitute for dairy fat is needed)
  - Coconut oil and MCT oil
  - Avocado or extra virgin olive oil (for dressings or homemade mayonnaise)
  - Omega-3 fish oils (either as fresh fish—e.g., wild-caught salmon—or in purified supplements)
  - Salad dressings and mayonnaise (organic or homemade)
  - Small amounts of other oils based on personal preferences (e.g., almond, macadamia)
- *Natural sweeteners:*
  - Stevia (liquid drops)
  - Monk fruit (also known as luo han guo)

22.11.3 Diet Supplementation

Rigorous ketogenic diets (10–12 net grams of carbohydrate) are known to be deficient in some nutrients. More moderate ketogenic diets may also fail to provide all the vitamins and minerals considered essential to health. Nutritional sufficiency can be assessed with any number of tools used by the functional or integrative team. Each team will have their own preferred system for optimizing health through supplementation. What follows are some general guidelines:

22.11.3.1 Vitamins

Ensuring adequate intake of fat-soluble vitamins A (retinol), D_3, gamma tocopherol vitamin E, and K2 is important in any diet. Serum levels of these and other vitamins can be included in baseline assessments. Routine monitoring of serum levels of 25-hydroxyvitamin D to ensure optimal (as opposed to "sufficient") levels is already included in most functional and integrative protocols.

22.11.3.2 Minerals

Ketogenic diets have a diuretic effect and it is common, especially in the early weeks and months, to note some disruption in electrolyte balance. Calcium, magnesium, potassium, and sodium may all need to be supplemented, preferably as food (e.g., salted bone broth). However, food sources may not provide sufficient intake. Consider supplementation after screening an individual with blood tests:

- Electrolyte panel
- Calcium, serum
- Calcium, ionized
- RBC magnesium
- Parathyroid hormone (PTH)—If calcium is >10, consider PTH to rule out secondary or primary hyperparathyroidism.

22.11.3.3 Gut Health

As mentioned previously, comorbidities such as gallbladder disease, history of cholecystectomy or poor fat digestion should be addressed proactively. At this time, there are few guidelines specifically addressing the use of prebiotics or probiotics or constipation for people following ketogenic diets. Instead, each practitioner should address the needs of the individual in determining recommended foods and supplements. For example, clients/patients with insufficient diamine oxidase enzyme may not tolerate certain histamine-producing species of bacteria. Risk/benefit assessment here is also crucial for those in active cancer treatment or with impaired immune function.

22.11.3.4 Digestive Aids

Some individuals will need supplemental digestive enzymes to support fat digestion. For example, certain patients may benefit from a pancreatic enzyme that is high in lipase or from the inclusion of an emulsifier, such as non-GMO sunflower oil lecithin. Ox bile is another consideration for individuals post-cholecystectomy or with bile deficiency; however, this may not be well-tolerated and should be monitored for side effects. Other digestive aids are situation-specific: for example, some individuals may benefit from betaine HCl supplementation.

22.11.3.5 Herbs and Botanicals

Oversight by the functional or integrative team is essential particularly if patients are working with multiple teams and providers to address complex health issues. All contraindications (including drug/herb and herb/herb interactions) also need to be assessed and monitored at initiation and over time.

22.11.3.6 Antioxidants

The ketogenic diet has unique anti-inflammatory effects that should be considered when developing protocols using antioxidants. The ketogenic diet's decreased fruit and vegetable intake presents a common lack of intake of phytonutrients, fiber, and vitamin C that should be considered when developing an intervention. Also, antioxidant supplementation may be contraindicated in those undergoing pro-oxidant cancer treatments.

22.12 Variations of the Ketogenic Diet

There are some scenarios where adopting a variation of the classic ketogenic dietary may better fit the patient's needs, especially when fat is not well-tolerated or weight loss is not desirable [67]. Patients should still be counseled to avoid sugars and grains but may opt to include small portions of legumes, fruits, or root vegetables. Another approach to limiting weight loss is to allow a greater percentage of calories from protein (though this may not be recommended for patients with cancer). A liberalized plan may also be the best

option for active or athletic individuals, especially if there is a substantially higher energy requirement. Here, a moderate plan might include more protein and carbohydrate as well as more total calories as fats and oils at each meal. Commercial ketone supplements are another option, especially for athletes who need a high-calorie snack before an event or workout.

22.12.1 Atkins Diet [44, 67]

The Atkins diet is a low-carbohydrate plan primarily aimed at those who want to lose weight. In Phase I (Induction), net carbohydrate intake is kept at or below 20 total grams and there is no requirement to divide that amount equally between meals. Atkins provides a list of acceptable induction foods. There are no specific guidelines for quantity or quality of fat or protein intake although more recent iterations of the diet do emphasize better quality choices. Despite detractors' claims that the Atkins plan is a kidney-damaging high-protein diet, years of research suggest that most people do not consume significantly more protein than they do on a standard diet. The combination of carbohydrate restriction along with a moderate increase in fat and protein intake results in a calorie deficit that most times leads to weight loss. Since the diet also has a diuretic effect, weight loss in the first few weeks can be exhilarating for people who have tried—and failed—other weight loss diets. It is important to note, though, that most individuals following an Atkins pattern do not achieve the low glucose or insulin levels seen with a more rigorous adherence to a ketogenic diet.

22.12.2 Modified Atkins Diet

The modified Atkins is a version of the Atkins plan that was developed and is now promoted by Dr. Eric Kossoff, an epileptologist at Johns Hopkins Hospital [68]. He was responding to the growing demand for a simpler ketogenic plan that did not require children to be hospitalized or fasted during initiation of the diet. His plan is also more user-friendly with adolescents and adults, few of whom were compliant to the restrictions used with younger children. In this version, carbohydrate intake is still low—initially 10–15 g of carbohydrate per day [68]. There are no specific guidelines for either fat or protein. This more relaxed approach to meal planning also makes it easier for families to dine out and travel. The modified Atkins for epilepsy is still viewed as a medical diet, and as such it is overseen by a team of specialists that include (at a minimum) a neurologist and a registered dietitian.

Over a decade of experience with the modified Atkins has now shown it to be a safe and efficacious alternative to the classic ketogenic diet therapy in epilepsy [67]. A recent 4-year study describes the challenges as well as the side effects of therapeutic ketogenic diets, including the modified Atkins. The authors concluded that these diets may be feasible, effective, and safe as long-term therapies in adults, which addresses some of the concerns of medical professionals who question the safety of keeping carbohydrate intake low over an extended period of time [67].

Published data also indicates that blood glucose levels range higher and ketosis is not as strong when the diet is liberalized to include more protein. This appears to improve compliance and has minimal impact on outcomes in adults choosing this pattern as a dietary therapy for epilepsy. The modified Atkins may also be a better choice than the classic ketogenic diet for those with compromised health status or complex medical conditions that prevent them from adhering to a more rigorous plan. Less frequently used variations include low-glycemic and medium-chain triglyceride versions of the diet (see ► Sect. 22.4).

The Cyclical Ketogenic Diet and Feast/Famine Cycling [7, 69, 70]

There is a great deal of interest in this option, which is promoted primarily through online forums and books directed at athletes and fitness enthusiasts. Simply put, the cyclical ketogenic diet is a technique to enhance muscle glycogen storage by maintaining a ketogenic diet during 5 days of intensive training then rebuilding stores with 2 days of carbohydrate-loading. Cycling may have merit for that application, but one possible downside is that keto-adaptation may take months, and cycling in carbohydrates may interfere with this process. Cycling may also lower resolve and commitment to a ketogenic plan.

Feast/famine cycling has been proposed as an option for individuals with metabolic disorders other than cancer, such as diseases of insulin resistance. This plan allows a day or two every week of higher carbohydrate and protein intake followed by a return to a low-carbohydrate or ketogenic plan. There is little agreement as to which foods—and in what amounts—should be included on feast days. One of the downsides of cycling is that it may disrupt the metabolic reprogramming associated with keto-adaptation. It also has the potential to lower resolve and commitment to the ketogenic plan.

22.13 Diet Ratio

Ketogenic diets are calculated using either a macronutrient *ratio* or a macronutrient *distribution*. From the beginning of its use in epilepsy, diet *ratio* reigned. Children were most often started on a classic 3:1 or 4:1 ketogenic diet, meaning that every meal was carefully planned so that the amount of fat *grams* was 3 or 4 times the number of combined carbohydrate-plus-protein *grams*. [38].

Diet ratio can be confusing, primarily because the ratio is based on a system—gram weights of macronutrients—which is foreign to the public at large, which is more accustomed to thinking of diets in terms of calories, not grams. Diet ratio was developed as a tool for registered dietitians to use in calculating a ketogenic diet prescription for a child with

epilepsy based on that child's individual protein and energy needs. Discussions of diet ratio migrated from the epilepsy world to scientific research where it is still sometimes used to describe diets used in both animal models and humans.

22.14 Diet Macros

More recently, another way of designating diet macronutrients has grown in popularity as use of the ketogenic diet has expanded to applications beyond epilepsy. In the fitness world, macronutrients (or "macros" as they are more commonly called) quickly became the preferred way to describe the distribution of macronutrients in low carbohydrate and ketogenic diets. In this model, macros are assigned a percentage based on *calories*, not *grams*. For example, in a 1600 calorie ketogenic diet, carbohydrates typically make up 5% of total calories (i.e., 80 calories, which represents 20 g). Obesity medicine specialist Dr. Eric Westman, along with researchers Eric Kossoff, Jeff Volek, and Stephen Phinney, refer to diet macronutrients in grams [20, 38, 48, 53].

Macronutrient distribution is most often viewed as more intuitive and user-friendly than diet ratio. Plus, the conventional nutrition community was already familiar with the Acceptable Macronutrient Distribution Ranges (AMDR) guidelines so it did not require further explanation to make it understandable to the public. Having a common language also made it much easier to compare the standard distribution with that of a ketogenic diet.

As illustrated above, each macronutrient is assigned a distribution range that represents its percentage of total calories in the diet. For example, 80% fat in a 1500-calorie plan amounts to 1200 calories (approximately 133 g of fat), while 80% fat in a 2500-calorie plan is 2000 calories (approximately 222 g of fat). Even though both of these diets are 80% fat, the increase in calories in the latter requires another 89 g of fat—an increase of more than 6 tablespoons of fat per day.

Protein as a percentage of the total calories may vary as well, but the absolute amount is in a narrower range as protein targets in a ketogenic diet are determined either by ideal body weight or lean body mass, not on total energy needs. Carbohydrates, as a percentage of the total calories, vary depending on two factors: total calories and diet rigor.

Ketogenic Diet Therapy for Children and Adolescents

There is a large body of work, including a consensus statement [38–40], that sets clear guidelines and protocols for initiation of the ketogenic diet for children and adolescents with intractable epilepsy. In the US, The Charlie Foundation is the major online resource for families and practitioners interested in working with this very special population. In the UK, the partner foundation is Matthew's Friends. Implementation of the diet for other applications requires cooperation and support of the child's medical team which should include an experienced keto dietitian or nutritionist. A specialized meal planning tool, the KetoDietCalculator (KDC), developed by Beth Zupec-Kania, consultant nutritionist for The Charlie Foundation, is available to registered clinics and dietitian/nutritionists. Using patient demographics, the KDC is used to calculate the initial diet prescription. Other features include a moderated helpline for questions from nutrition professionals, a vetted macronutrient database, lists of low- and no-carb dietary supplements, a selection of standard ketogenic meals, and flexibility to create new meals and meal plans based on a child's individual needs. The dietitian or nutritionist overseeing the child's diet can grant access to the KDC to allow families to create their own meals that adhere to the diet prescription. (Use of the KDC has expanded to include adults.)

22.15 Short-Term Versus Long-Term Maintenance

The clinical trials of the late twentieth century identified the potential side effects of the ketogenic diet when used for up to 2 years in children with epilepsy [38]. (It is important to note that a subset of children receive enteral nutrition with commercial formulas rather than whole foods.)

Reported side effects include:

- Minor metabolic abnormalities (hyperuricemia, hypocalcemia, hypomagnesemia, decreased amino acid levels, acidosis)
- Gastrointestinal symptoms (vomiting, constipation, diarrhea, abdominal pain)
- Carnitine deficiency
- Hypercholesterolemia
- Renal calculi

Other observations that may or may not be related to the diet include slowed linear growth in children, pancreatitis, and a few reported cases of cardiomyopathy and elongated QT interval (associated with selenium deficiency) [71, 72]. There are also reports in the literature of side effects, including osteoporosis, associated with long-term maintenance on the diet, but these are mostly associated with syndromes or inborn errors of metabolism, most of which limit physical activity or involve the use of medications that deplete or interfere with mineral absorption. Food allergies to dairy proteins would also limit the amount of calcium available through diet.

The growing body of research encompassing preclinical and anecdotal reports suggests that the diet is safe in the short-term but research to examine long-term effects lags behind. In fact, the lack of research identifying effects and outcomes from long-term adherence is one of the main criticisms of the growing number of studies that show a clear benefit to carbohydrate-restricted and/or ketogenic diets as

treatment for type 2 diabetes and metabolic syndrome. Concerns about long-term side-effects of ketogenic diets have been raised and addressed in part by a long-term study conducted by physicians affiliated with the Johns Hopkins University School of Medicine and the Johns Hopkins Adult Epilepsy Diet Center. Their findings that ketogenic and modified Atkins diets were safe, feasible, and efficacious in the study population were published in the journal *Epilepsy Behavior* [68]. More questions will be answered and others will be framed within the context of studies similar to this one.

22.16 Transitioning to a Ketogenic Diet

Adaptations to ketosis fundamentally alter the manner in which the body processes nutrients. The impact of the transition must be considered in light of each individual's health history and current status. In order to ensure the best chance of success, the nutritionist should counsel the patient prior to initiating the diet and provide ready access to the team via email, phone calls, texts, or other predetermined means of communication.

22.16.1 Option #1: Fasting

Fasting has known therapeutic benefits that are beyond the scope of this chapter. One such benefit is the reduction or elimination of seizures in individuals with severe epilepsy. In fact, a short fast was part of the original Wilder/Peterman protocol [73] developed in the 1920s for initiating the diet as a treatment for epilepsy. Although most ketogenic centers for epilepsy no longer require a fast, it is still commonly used in other applications of the diet, particularly for weight loss and cancer. A fast quickly lowers serum levels of glucose and insulin while simultaneously upregulating fatty acid oxidation and ketogenesis. Fasts have a diuretic effect, which is motivating to individuals with a weight loss goal. A fast can also help cancer patients retain or regain a sense of control over a health crisis that is otherwise overwhelming. Engaging in an extended water-only fast may inhibit angiogenesis, which may in turn slow progression of the disease. Modified fasts are a less rigorous option and can include fluids such as salted broth with added fats or oils.

The benefits of fasting need to be weighed against the risks and potential downsides. The functional or integrative team needs to consider the patient's health and nutrition status, contraindications, comorbidities, and social support before recommending a fast. Before initiating a fast, the patient needs to be educated regarding what to expect and how to interpret the physical symptoms that they are likely to experience. They should be counseled to end the fast if continuing would endanger themselves or a person under their care, such as a child or disabled adult. They should also have some prior practice in the use of a home blood glucose meter. Ketone levels can also be assessed, either with blood ketone testing or urine test strips. And finally, the patient needs to have a plan in place to maintain ketosis once the fast has ended.

Despite the patient or practitioner's enthusiasm for a fast, there are medical reasons (such as gallbladder disease) why fasting may be a poor choice. For example, fasting is not a viable option if the patient is older, in frail health, recovering from surgery, or in need of medication that must be taken with food. Individuals should proceed cautiously if they are already below normal weight or have experienced a recent unintended weight loss. Consider also the risks for those with a history of heart arrhythmia or palpitations, or if prior drug therapies have caused an elongated QT interval, as fasting can cause some initial disruption in electrolyte balance and heart rhythm. Fasting should not be practiced by women who are pregnant or lactating. This is only a partial list—further investigation into health history is strongly recommended.

22.16.2 Option #2: A Rigorous Ketogenic Diet

Although fasting is the quickest way to reach ketosis, starting with a classic ketogenic diet will also facilitate a quick shift to ketosis [73]. The patient should be encouraged to eliminate all non-essential carbohydrates from the diet in order to keep net carbs at or below 16–25 g per day. Another factor in this decision relates to the glycemic index and glycemic load of the foods that the integrative or functional team is recommending. For example, most carbohydrates from leafy greens and a few cruciferous vegetables, such as cabbage, have a negligible impact on glucose levels. In contrast, blueberries will elicit more of a glycemic response.

The transition to the ketogenic diet will be smoother if the patient is educated as to which foods are included in a very-low-carbohydrate diet and which should be limited or eliminated entirely (see the food lists in ▶ Sect. 22.11). Those with prior experience in whole-food cooking will already have most of the skills needed to plan and prepare ketogenic meals. Many favorite recipes can be modified by substituting keto-friendly ingredients for the more traditional carbohydrate-loaded ones; for example, "riced" cauliflower can be used in place of traditional rice. Protein portions may need to be tapered down during this transition. Tracking food intake with an app or other diary is highly recommended as the feedback this provides is invaluable to both the patient and the practitioner. As with fasting, it is important to monitor blood glucose and track ketones.

22.16.3 Option #3: A Slow Transition to Ketosis

Patients are often nutritionally compromised by their diseases or treatments or otherwise unable to make all the changes needed in order to begin with a rigorous ketogenic

diet [73]. A slower transition may also be more appropriate if the patient is moving to a ketogenic plan directly from a standard diet that is heavily reliant on packaged, processed, or pre-prepared foods. They will often need more time to properly stock their kitchen and pantry.

Patients can start by eliminating grains, starchy gluten-free flours, and added sugars of any kind. They should also reduce portions and servings of starchy vegetables, legumes, and fruits while simultaneously adding a tablespoon or two of a healthy fat or oil to each meal. Once they are comfortable with the added fats, they can begin to phase out other concentrated sources of carbohydrates. This is also a good time to introduce medium-chain triglyceride oil to the diet. Protein targets should be clearly prescribed. With ongoing support and monitoring from the nutrition specialist, the patient is less likely to experience side effects that often interfere with compliance.

22.17 Potential Side Effects of the Transition

The integrative or functional medicine team should educate each patient as to potential side effects of the transition. Addressing these proactively can ease the burden of symptoms and improve patient compliance to the program.

22.17.1 Hunger and Cravings

One of the most vexing problems for people following standard high-carbohydrate diets is the impact of hormonal signaling on appetite. This signaling is subjectively experienced as hunger and cravings. However, a ketogenic diet is associated with changes in hormone signaling that effectively dampen appetite, which greatly reduces these symptoms. If the patient is generally healthy and at (or above) a normal weight, this reduction in appetite is welcome. However, if weight loss is contraindicated, efforts should focus on ensuring an adequate intake of nutrients prior to Day One of the transition to the diet.

22.17.2 "Keto Flu"

In the first few days or weeks, many people experience symptoms that are collectively (and vaguely) referred to as "keto flu." This usually involves some combination of headaches, fatigue, lightheadedness, poor concentration, muscle cramps, body aches, insomnia, and constipation. At the system level, the decrease in insulin alters the manner in which the kidneys handle sodium, which in turn leads to a greater loss of fluids and electrolytes in urine. Patients should be counseled to replace fluids and replenish electrolytes, especially sodium [74]. At the cellular level, epigenetic changes prompted by the shift to ketosis result in an increase in the number of transporter proteins that allow for a greater influx of ketone bodies into the cytoplasm. Within days or weeks, mitochondria respond to this change by upregulating production of the enzyme needed to metabolize ketone bodies for energy which in turn helps to resolve these symptoms.

22.17.3 Hypoglycemia

Within hours of the last moderate- to high-carbohydrate meal, a drop in blood glucose levels will stimulate glycogenolysis [23]. Once liver glycogen is depleted, glucose homeostasis is maintained by the endogenous production of glucose, mostly through gluconeogenic activity in the liver. Some people experience a transient dizziness or a lightheaded feeling during the transition due to low blood glucose levels. Most often, glucose levels self-correct quickly. Patients should be provided with a blood glucose home testing kit (meter, strips, finger stick device, lancets) and instructed in best practices for testing. A low glucose reading (50–60 mg/dL) *accompanied by symptoms such as shaking, sweating, or lethargy* can be treated by dosing with two tablespoons of apple or orange juice. If low levels do not resolve in 30 minutes or if symptoms persist, a second dose of two tablespoons may correct the problem. If hypoglycemia persists, the patient should be seen by a physician to rule out acidosis or a previously undiagnosed metabolic disorder. (Readings of 50–60 mg/dL are virtually without symptoms once the brain begins utilizing ketone bodies.) Be aware that children deplete glycogen reserves more quickly and are more likely to be symptomatic. For this and other safety reasons, it is highly recommended that children starting therapeutic ketogenic diets do *not* start with a fast or a sharp reduction in carbohydrates unless they are under the watchful eye of a physician.

One Essential Caveat for Those with Diabetes
Individuals with type 1 diabetes or poorly controlled type 2 diabetes, with or without frequent hypoglycemic episodes, MUST NOT adopt a ketogenic diet unless they are under the supervision of an experienced ketogenic team. Some diabetics may also be at a higher risk of "hypoglycemic unawareness"—another reason to work with a specialist.

22.17.4 Acidosis

Mild and temporary acidosis may occur during the transition to a ketogenic diet, especially if it is initiated with a fast [7]. This is usually limited to a slight and easily reversible disruption in blood pH. This uncomplicated metabolic disorder is not the life-threatening condition known as diabetic ketoacidosis (DKA), a severe derangement that manifests as extremely high blood glucose (usually well over 200 mg/dL) along with extremely high levels of blood ketones (exceeding 14 mmol/L). DKA most often results from a shortage of insulin in people with type 1 diabetes or poorly controlled type 2

diabetes [74]. Another type of metabolic acidosis is associated with the use of a class of diabetes medications called SGLT2 inhibitors (such as Invokana) which should be discontinued—*under medical supervision*—prior to initiating any low-carbohydrate diet. In fact, practitioners managing a patient with diabetes need to be fully informed about any proposed change in diet.

Alcoholic ketoacidosis (AKA) is a form of metabolic acidosis characterized by an elevated anion gap, elevated serum ketone level, and normal or low blood glucose levels [74]. Practitioners should screen for prior history of alcohol abuse and/or AKA and advise against drinking alcohol during the transition.

Acidosis may also occur during the transition or at times of illness or other metabolic stress that results in a sharp increase in ketones (above 5 mmol/L), usually accompanied by dehydration. High ketone levels by themselves may not indicate acidosis but should be suspected when seen concurrent with symptoms that include extreme lethargy, nausea, vomiting, flushing, panting, and a rapid or irregular heart rate. Mild acidosis can be treated with two tablespoons of apple or orange juice as well as ½ teaspoon of baking soda in a glass of water. However, if symptoms persist, the patient will need to be seen by a physician that can assess blood chemistries, such as CO_2 levels and anion gap.

As is the case with hypoglycemia, children are more likely than adults to experience acidosis during the transition or as a result of loss of fluids (diarrhea or vomiting) during an illness [4, 37]. Parents should be educated about this and provided with a sick day protocol and an emergency phone contact.

22.17.5 Dizzy, Lightheaded, or Shaky

As noted earlier, these symptoms may indicate hypoglycemia, but they can also be due to a drop in blood pressure during the transition. Patients should be advised against engaging in activities that require balance or a sudden increase in effort, such as climbing ladders or working out with weights. If these symptoms persist for more than a few days, a healthcare practitioner should assess blood pressure [67, 72–74]. It is also crucial that medical professionals monitor all individuals who are taking medications to control high blood pressure. Another consideration: The diet has a diuretic effect which may overlap with the impact of diuretics used to manage high blood pressure.

22.17.6 Constipation

Most people have fewer bowel movements on a ketogenic diet than they may have had previously. This anticipated change in what is known as "regularity" is not the same health issue as true constipation (straining to pass hard stool). That said, true constipation may worsen with the initiation of a ketogenic diet and must be addressed proactively. Patients should be counseled to stay well-hydrated and to choose foods that are naturally high in fiber. (Use caution with fiber supplements.) Certain medications and nutritional supplements (such as calcium carbonate) can also contribute to constipation, while other supplements (such as certain forms of magnesium) can ease symptoms by drawing more water into the colon [75].

22.17.7 Heart Rate or Rhythm Changes, Including Palpitations

A change in blood volume brought on by dehydration and the loss of electrolytes in urine may cause the heart to beat faster and/or harder [76]. Salted broth and proper hydration can help to replenish fluids and electrolytes. Dehydration and an imbalance in electrolytes can trigger an episode in those with pre-existing heart disease or rhythm disorders, such as atrial fibrillation. Also, risk/benefit assessment should include a cardiac evaluation in individuals who have received medications known to prolong QT interval—this potentially fatal condition should be ruled out before transitioning a patient to a ketogenic diet [71, 72].

22.17.8 Change in Exercise Tolerance or Physical Performance

Patients should be advised to limit physical activities until transition symptoms have resolved. Instead of intense workouts or training, they can stay active with gentle walking, cycling, or lap swimming. However, some individuals will choose instead to engage in more vigorous activity. For them, the transition may be a source of frustration as their muscle tissue adapts to the increase in fatty acid oxidation and the availability of ketone bodies as a preferred metabolic fuel. Low carbohydrate and ketogenic diets appear to confer a metabolic edge in many sports, especially endurance events [7].

22.17.9 "Keto Rash"

Pruritis pigmentosa, a.k.a. "keto rash," is an uncommon and poorly understood potential side effect of the diet. There is some speculation as to cause—either acetone in sweat or a change in the skin microbiome. Reducing the level of ketosis or discontinuing the diet will resolve the symptoms [73, 74].

22.17.10 Increased Risk of Kidney Stones and Gout

There is an increased risk for certain types of kidney stones, especially for those with a personal or family history. This can be addressed prophylactically with a prescription medication containing citric acid and potassium citrate and dietary supplementation of magnesium citrate and vitamin K2. However, there are many contraindications to use especially for those with compromised renal function [76].

In the first few weeks or months of the diet, there may be a rise in uric acid levels due to competition between uric acid and ketone bodies for excretion in the urine [77]. Although this is often expressed as a concern by physicians, there is no evidence that it will progress to gout in individuals without a personal history of this disease [77].

22.18 The First Few Weeks: The "Make or Break" Period

The first few weeks of the ketogenic diet is often the "make or break" period so it is crucial to foster a strong commitment at the start. Along with commitment, the patient needs the following tools and strategies that enhance both compliance and accountability [73, 78]. Along with these items, an accessible nutrition coach can answer the questions that inevitably arise during this period.

Keep It Simple

The transition to a ketogenic diet usually involves a considerable amount of effort on the part of the patient. Changes can feel overwhelming at the start, so it is often best to offer simple recipes and meal preparation tips that allow the patient to put a meal on the table with a minimum amount of time and effort. Variety is not usually a priority in the first few weeks and many people will opt to recycle the ketogenic meals that they find most palatable and easiest to prepare. Ongoing education and support will help to move them toward more variety and better quality once they are comfortable with basic meal planning.

Patients can start with one fully ketogenic meal per day and build from there. Most people find breakfast the easiest meal to adapt; for example, eggs cooked in butter garnished with grated cheese and perhaps a strip or two of bacon served with a steamed or sautéed vegetable and a drizzle of added oil.

Review the following actions:

- Have they completed a pantry sweep, removing or relocating non-keto foods?
- Did they buy new keto-friendly food staples?
- Have they obtained a blood glucose meter? If so, have they practiced with it yet?
- What is the plan for testing glucose and ketones in these first few weeks?
- Do they have a kitchen gram scale? If so, are they familiar with how to use it?
- Do they have access to meal planning tools and recipe resources?
- If the idea of structured meal planning is likely to be too daunting at the moment, have they been provided with a simple meal template customized to their macronutrient prescription?

22.18.1 Testing Glucose and Ketones

Testing blood glucose and ketones is strongly encouraged in the first few weeks of the transition as it offers an objective and quantifiable means of assessing whether or not the patient is achieving the goal of lowered blood glucose and elevated ketones. Glucose and ketone measures also help the patient and practitioner to troubleshoot issues that arise [73].

22.18.2 Testing Blood Glucose

There are currently two methods of testing blood glucose: glucometers and continuous glucose monitors. By far, the least expensive and most convenient testing method is with the use of a glucometer, also known as a home blood glucose meter. Specialized testing tools, such as watches and contact lenses, are currently in development and will reduce or eliminate the need for finger stick testing.

Patient Instructions for Testing Blood Glucose in the First Few Weeks of the Diet

Although blood testing of glucose and ketones is not essential in every application of a ketogenic diet, the practitioner may still recommend testing as it provides clear, objective data. What follows is one recommendation for a testing schedule:

- Using the blood glucose meter, test and record fasting blood glucose (FBG)
  - In these early weeks, expect fasting glucose measurement to be erratic
  - Expect levels to become low and steady with keto-adaptation
- Test and record blood glucose in the middle of the afternoon, either before a meal or least 2 hours after a meal
- Test blood glucose before bedtime
- If the glucose measurement is uncharacteristically high or low, immediately retest using a new drop of blood
  - If the two measurements are close, take the average
  - If the second measurement matches the general trend, record that one

If using a proprietary drink formula with oils, fats, and coffee to delay the first meal of the day:

- Test and record fasting blood glucose then test again just before the first meal. Most likely, the second measurement will be lower than FBG. If the pre-meal test is *higher* than FBG then the length of the fast may be too long. (Do not rely on a single day's numbers: test several days before making changes in meal timing.)

22.18.3 Ketone Testing Tools [73]

As described earlier, there are three types of ketone bodies: beta-hydroxybutyrate (detected in blood), acetoacetate (detected in urine), and acetone (detected in breath).

22.18.3.1 Blood Ketones

Testing blood levels of beta-hydroxybutyrate is the standard used in research and this method has gained widespread acceptance in therapeutic ketogenic diets. This requires the use of ketone test strips that are paired with a meter that tests both glucose and ketones.

Testing Blood Ketones

- Test and record fasting ketone levels
- Also test ketones an additional two or three times a week—either in the middle of the afternoon (before a meal or at least 2 hours after a meal) or at bedtime
- The threshold for nutritional ketosis is 0.5 mmol/L and the upper level is considered to be in the range of 3–5 mmol/l
- Levels at 5–7 mmol/L are associated with fasting or starvation
- Levels above 7 mmol/L are not common in adults unless they are supplementing with exogenous ketones.

22.18.3.2 Urine Testing

Urine test strips use nitroprusside to detect the presence of acetoacetate in the urine. Nitroprusside changes to a pink tone ranging from a blush of color to deep purple—the darker the shade of purple, the more acetoacetate is present. Urine test strips are inexpensive, non-invasive, and easy to use. While urine ketones are not as accurate a measure of ketosis as blood testing, the strips can still be used to check compliance and improve accountability. (Note that testing within a few hours of vigorous exercise or when hydration levels are either higher or lower than the norm may not yield accurate results.) Results using urine strips are typically more valid in the early weeks and months, before keto-adaptation is complete.

22.18.3.3 Breath Analyzer

Specialized breath analyzers can detect the presence of acetone, another of the ketone bodies. This technology uses a small handheld device which connects to a computer or other USB-supported device. Although these devices are convenient and reusable, they do not always correlate with blood levels of beta-hydroxybutyrate. The later iterations are more precise tools though they are more expensive to maintain. Some people, notably athletes, prefer this type of testing as part of their biohacking routine as it is a somewhat quantifiable marker of ketosis. However, some of the first-generation devices may not be good tools for individuals whose lung capacity is impaired by asthma, age, or disease.

22.19 Troubleshooting

Challenges that arise in the first few weeks or months of the diet need to be addressed on a case-by-case basis before they become obstacles to compliance. What follows is an overview of the most common transition symptoms along with suggested actions.

22.19.1 Ongoing Flu-like Symptoms

The decrease in insulin levels alters the way in which kidneys handle sodium, producing a diuretic effect and concurrent loss of electrolytes [74]. Sodium and chloride can be replenished by adding salt to homemade broth. Potassium supplements, including potassium citrate, may also be used along with the broth but may not be appropriate for patients taking potassium-sparing drugs, such as Lisinopril. Magnesium supplementation should be considered for all patients but may be contraindicated in those with certain kidney diseases [75, 76]. Also, ensure adequate intake of calcium, preferably through food.

22.19.2 Hunger between Meals

Hunger and craving are common in the first few weeks. If they continue, it may indicate that the patient is not yet in sustained ketosis. Increase the frequency of ketone testing to detect any drop in ketone levels below the threshold of 0.5 mmol/L. Hunger may also persist in those who are slower to adapt to the changes in hunger signaling associated with keto-adaptation. Another common reason for persistent hunger is inadvertent non-compliance to the diet. Review the food diary for sources of hidden carbohydrates especially in beverages and food-based supplements. Also confirm that protein intake is within the suggested limits. Caloric restriction adopted along with a therapeutic ketogenic diet may result in lingering hunger—ensure that adequate amounts of fat are included in the plan.

22.19.3 Food Cravings

Determine which foods the patient is craving. If it is a sweet treat, provide suggestions for keto-friendly substitutes, such as fat bombs or keto treats. If the craving is for salty or crunchy foods, suggest sour pickles, fried pork rinds, or keto-friendly crackers with a crunch. Some people crave protein: recheck macro calculations and food records to be sure that the protein target is accurate and met through the diet. Protein foods, especially protein in eggs and dairy, will also elicit an

insulin response even in the absence of carbohydrates. In some individuals, this response may be exaggerated enough to suppress ketone production. (Cravings specific to cheese may be influenced by other factors, such as opiate-like receptors for beta-casomorphins in the brain.) [79].

22.19.4 Unsustainable or Rapid Weight Loss

Weight reduction is a goal for many people who adopt a ketogenic diet, but unsustainable or rapid weight loss is not the goal of a therapeutic ketogenic diet [73]. Weight loss that is greater than two pounds a week, or weight loss of any amount in someone who is already below ideal weight, must be slowed or stopped. This is especially important post-surgery or with metabolic dysregulation associated with sarcopenia and cancer cachexia.

Resistance training is anabolic in working muscle. Therefore, it is crucial to advise patients to consider some type of strength training to preserve or build muscle mass especially during periods of rapid weight loss. This may be as basic as the use of resistance bands or light weights ideally under the watchful eye of an experienced fitness trainer that can provide feedback as to proper form and ideal degree of resistance. Exercises may need to be modified to match them to the energy level and current fitness of each individual.

To slow weight loss (or encourage slight weight gain), consider adding a small serving (50–60 g) of a low glycemic index fruit or legume (GI less than 40) to one meal a day. The patient should assess their glucose response to that meal by testing blood glucose just before the meal and again 45 minutes to an hour after the meal. Expect to see a rise in glucose of about 25–30 mg/dL—this should be sufficient to briefly stimulate insulin. Most likely, this will temporarily reduce ketone levels, but this downside may be offset by the opportunity to preserve fat stores, restore glycogen, or regain lost weight. If glucose rises by more than 25–30 mg/dL, then reduce the portion slightly and test again on another day. Test only one meal a day. This will have less of a detrimental effect on ketosis.

Weight loss may accompany reliance on MCT oil as a primary source of dietary fats. MCT is readily converted to ketones but excess ketones are excreted in the urine which reduces the energy value. If weight loss is too rapid or otherwise undesirable, counsel patients to consider MCT oil as a supplement, or "bonus."

22.19.5 Spikes in Glucose (a Rise of >25–30mg/dL) with a Meal or Snack

Check the labels on packaged foods or low-carb snack bars to identify any ingredients that might be causing glucose spikes. Look for sugars or problematic fibers, such as isomaltooligosaccharides (these are often assumed to be indigestible sugars but are known to raise blood glucose in some individuals) [78, 80]. Sauces and dressings added to restaurant meals often contain sugars or flours. Also, be wary of foods promoted as "sugar-free" and marketed to people with diabetes, as these may not be keto-friendly.

22.19.6 Steroid Medications (e.g., Prednisone, Dexamethasone, or Hydrocortisone)

Prednisone and dexamethasone are commonly prescribed to control inflammation, and hydrocortisone may be prescribed as a replacement hormone if cortisol levels are low [81]. All steroid medications cause a rise in glucose levels and should only be used under the supervision of a medical doctor. Furthermore, any attempt to discontinue or wean from these drugs must be done under the direction of the medical team.

22.19.7 Dropping out of Ketosis

Use of an online tracking tool, such as Cronometer, can help patients with both compliance and accountability by identifying food choices or portion amounts that are not in keeping with their ketogenic plan. Check to be sure that macronutrient intake is divided fairly evenly between meals. Women may also drop out of ketosis during the menstrual cycle due to normal shifts in hormones that may be associated with transient insulin resistance [78].

22.19.8 Hidden Carbohydrates in Medicines, Supplements, or Hygiene Products

A pharmacist can provide information about the carbohydrate content of medications. Also look for sugars, starches, and sugar alcohols (aside from xylitol or erythritol) in the ingredients list on food and supplement labels. Visit the Charlie Foundation website [39] and download their list of low-carb and carb-free supplements and personal hygiene products.

22.19.9 Nausea or Vomiting

Gastrointestinal diseases and disorders can trigger the release of stress hormones that stimulate gluconeogenesis. If nausea or vomiting is due to cancer or cancer treatment, the doctor or oncology nurse is likely to prescribe antiemetics. However, if nausea appears to be diet-related, reduce the amount of fats and oils to a point that does not cause symptoms then gradually increase the amount, perhaps adding a high-lipase pancreatic enzyme, lecithin, and/or ox bile that will aid in digesting fat. Other strategies include spreading fat intake out over several small meals and snacks.

22.19.10 Dissatisfaction with Food Choices

Ketogenic diets are restrictive and patients often express boredom or dissatisfaction with the limited choices, especially at breakfast. Remind patients that they are not limited to traditional breakfast foods; any keto meal can take its place. Also, there are many keto cookbooks and online recipes that can spark new interest in those who are bored with current choices.

22.19.11 High Blood Glucose Levels

In the context of a ketogenic diet, fasting blood glucose levels over 85 mg/dL, or random blood glucose levels that remain over 90 mg/dL several hours after finishing a meal are considered high. Work through these questions:

- *Is it only fasting blood glucose that is high?* This can simply be due to the dawn effect, the normal circadian rise in cortisol that stimulates a release of glucose. Another possibility, but one that is poorly understood, may rest with what is referred to as *physiological insulin resistance* (more recently referred to as adaptive glucose sparing). Put simply, low fasting insulin concurrent with a rise in early-morning blood glucose may result in a higher than expected fasting number. High fasting numbers due to either the dawn effect or physiological insulin resistance typically drop within a few hours of waking, especially if the first meal of the day is delayed, as in time-restricted feeding. If this is the case, then no intervention is needed. However, high fasting glucose can also be due to consuming too much protein at the evening meal, particularly if that meal (or other food) is eaten within a few hours of bedtime.
- *Is the patient receiving chemotherapy or radiation, or recovering from surgery?* These are all systemic "injuries" and the body's response here is the same as for all other illnesses or injuries. Expect glucose levels to be higher than they would be in individuals who are not facing these additional challenges. Glucose levels will also be higher in individuals with extensive metastatic disease in cancer—lactic acid produced as metabolic waste from excessive fermentation of glucose is converted back into glucose by the liver. (High lactate also occurs in non-disease states; for example, as a byproduct of metabolizing muscle glycogen during intense anaerobic activities.)
- *Does the patient have a history of insulin resistance?* If so, circulating levels of glucose and insulin might remain higher than expected because cells are still less sensitive to insulin. These individuals may take longer to adapt to the diet. The chronic presence of insulin also suppresses ketone production, creating a vicious cycle. (Metformin, a prescription medication that helps lower blood glucose levels, also helps to restore insulin and is sometimes used concurrent with a therapeutic ketogenic diet. Note that individuals taking Metformin may see a drop in HDL cholesterol and serum levels of vitamin B_{12}.)
- *Is the patient consuming too few calories?* Rapid weight loss (greater than 5–7 pounds in the first 2 weeks) can be a red flag that calorie intake is too low. This may trigger hormones that upregulate glycogenolysis or gluconeogenesis. Reassess the diet prescription calculations and/or check the food diary to be sure that targets are being met.
- *Is the patient waiting too long between meals?* The ideal window for time-restricted feeding varies widely among individuals. Some people can routinely fast for 16–18 hours a day while others may be physically stressed by periods greater than 12–14 hours. Even in those who maintain a wider eating window, the length of time between meals may stimulate the production of hormones that contribute to a rise in glucose. To determine the ideal amount of fasting, the patient should be advised to take several blood glucose readings at various points in the day, preferably before meals, to detect any trends related to meal timing.
- *How well is the patient coping with stress?* External stressors directly and indirectly influence blood glucose levels. For example, fear activates the sympathetic nervous system which stimulates the production of epinephrine and release of glucose through glycogenolysis. Psychological stressors can raise cortisol levels which then upregulate gluconeogenic activity. Indirect stressors, such as poor sleep, can interfere with hormone regulation and insulin sensitivity. Physical activity, social connectivity, reduction in exposure to stressful environments, improved sleep, and meditation/prayer can all be effective ways to lower stress and improve blood glucose control and insulin sensitivity.

22.20 Conclusion

The development of the infrastructure needed to support widespread application of metabolic therapies, including the ketogenic diet, lags behind the science. Acceptance by a broader contingent of medical professionals remains elusive in large part due to the high cost of conducting human clinical trials that form the basis of most medical practice guidelines. As a result, insurance providers have been slow to provide reimbursement for healthcare professionals who offer these therapies. At the heart of this problem lies a pervasive belief, even among integrative practitioners, that ketogenic plans are inherently inferior to those that are viewed as a "balanced diet." This current nutrition paradigm should be re-evaluated within the context of the body of evidence pointing to an underlying mechanism common to most disease states: specifically, that epigenetic changes in gene expression induced by an overabundant supply of glucose contribute to a broad spectrum of conditions, including obesity, diabetes, cancer, and neurodegenerative disease.

Consumer demand not only in epilepsy, but in metabolic syndrome, neurodegeneration, cancer, and in high-performance athletes have pushed research further than previously and this is poised to continue.

The gut immune system has the challenge of responding to the pathogens while remaining unresponsive to food antigens and the commensal flora. In the developed world, this ability appears to be breaking down, with chronic inflammatory diseases of the gut commonplace in the apparent absence of overt infections. –Thomas T. MacDonald/ Giovanni Monteleone (2005). Immunity, inflammation, and allergy in the gut. *Science*, 307(5717), 1920–1925.

23.1 Introduction

The focus of this chapter is to explore the synergistic relationships, between the gastrointestinal system and the immune system, and their joint effects on systemic health and inflammation. Research in these areas is mushrooming. Current research indicates that 70% of the immune system is located in the gastrointestinal system (GIT) and in the cells in the gut lumen, which is the opening in the middle of the intestines [1]. This is called the gut-associated immune system (GALT).

Food plays an enormous role in our immune response. Matzinger's Danger model of immunity states that the function of the immune system is to distinguish between exposures that are dangerous and safe. Our tissues have two main responses to foreign exposures: to be tolerant or to send alarm signals. The immune system is tolerant to exposures nearly all of the time, yet when it determines that something is dangerous, it reacts [2]. Each day we eat pounds of food, which is a "foreign matter" to the body. Therefore, the food we eat each day is a main driver of immune response. The typical Western diet is inflammatory and begins the process of digestive imbalance.

Digestion is the river of life. When we cannot digest, absorb, and utilize nutrients from food, all tissues are compromised. Other players in the gut-immune system include the integrity of the gut barrier, the role of the gut microbiome, the cascade of immune responses that signal for healing and inflammation, gut motility, and the ability of the liver, gallbladder, and pancreas to perform. This review will provide a clinical introduction.

23.2 The Digestive System

The digestive tract is comprised of the mouth, esophagus, stomach, gallbladder, liver, pancreas, small intestine, large intestine, and anus. Its job is to take food we eat and to nourish each cell in the human body. This is a finely orchestrated process and, when working correctly, is something we pay little attention. When out of balance, we experience distress in the form of pain, gas, distension, inflammation, changes in bowel movements, and immune system activation.

23.3 The Digestive Process

Eating, also called ingestion or the cephalic phase, is voluntary when materials are put in the mouth. This is our portal for nearly all nutrients to enter the body and involves the mouth, teeth, tongue, parotid, and other salivary glands. Food choices are related to lifestyle, personal values, and cultural customs. This is our first immune contact: Does the food smell good, look good, and taste good? Is thorough mastication occurring?

Digestion occurs in the mouth, stomach, and small intestine and requires cooperation from the liver and pancreas. Mechanically, foods are chewed in the mouth and churned in the small and large intestine to break the foods into molecules that can be absorbed into the bloodstream and cells. The proper levels of hydrochloric acid, bile, enzymes, and intestinal bacteria are critical for full digestive capacity. Digestion can be supported with digestive enzymes, bitters, relaxation, and thorough chewing.

Secretion Every day, the walls of the digestive tract secrete about seven quarts of water, acid, buffers, and enzymes into the lumen (inside) of the digestive tract. Secretion occurs throughout the entire digestive tract. These secretions help maintain pH levels and send water into the gut to lubricate and keep things moving. They also provide enzymes to digest foods and facilitate the digestive process. Hydration is essential for this phase of digestion to work properly.

Motility Whatever we eat is squeezed through the digestive system by a rhythmic muscular contraction called peristalsis. Sets of smooth muscles throughout the digestive tract contract and relax, alternately pushing food through the esophagus to the stomach and through the intestines. Think of a snake swallowing a mouse. The process helps the food become acidified, liquefied, neutralized, and homogenized until it's broken down into usable particles. From the time you swallow, this process is involuntary and can occur even if you stand on your head. Irritable bowel syndrome, small intestinal bacterial overgrowth (SIBO), and gastroparesis are examples of altered motility disorders. Ginger, fiber, garlic, and an herbal product called Iberogast all help to stimulate motility.

Absorption occurs in the small intestine. Digested food molecules are taken through the epithelial cell lining of the small intestine into the bloodstream and through the portal vein to the liver, where it is filtered. From the bloodstream, it passes to the cells. Until food is absorbed, it is essentially outside the body – it is in a tube going through it. If the gut is inflamed, as with gluten intolerance or celiac disease, there can be malabsorption, which is typified by anemia, diarrhea, an inability to gain weight, and a lack of growth in children. Absorption is enhanced by healing intestinal permeability and utilizing a low-antigenic, low-inflammatory therapeutic diet until this healing has occurred.

Assimilation is the process by which fuel and nutrients enter the cells. The reason we eat food is to nourish each individual cell. Diabetes is a condition of poor assimilation. Assimilation is also enhanced by healing intestinal permeability and utilizing a low-antigenic, low-inflammatory therapeutic diet until this healing has occurred.

Elimination In digestion, we excrete wastes by having bowel movements (defecation). These wastes are comprised of indigestible food components, waste products, bacteria, cells from the mucosal lining being sloughed off, and food that has not been absorbed. Constipation and diarrhea are both examples of imbalanced elimination. Chronic diarrhea contributes to malnourishment. Chronic constipation is a sign of poor motility and can increase levels of beta-glucuronidase, which implies impaired phase II liver detoxification. Hydration, exercise, dietary fiber, probiotics, and prebiotics all enhance elimination.

When microbes enter the digestive system, they are confronted with several nonspecific and antigen-specific defense mechanisms (innate immune system) including peristalsis, bile secretion, hydrochloric acid, mucus, antibacterial peptides, and immunoglobulin A, also known as IgA. This stops most microbes and parasites from infecting the body.

23.4 The Stomach and the Immune System

The stomach contains two main immune protective substances: gastric acids – also called hydrochloric acid – and pepsin. After ingestion of food, this becomes the second line of immune defense.

Protein molecules are composed of chains of up to 200 amino acids strung together. Hydrochloric acid (HCl), produced by millions of parietal cells in the stomach lining, begins to break apart these protein chains. HCl also digests bacteria, fungi, and parasites that come in with our food, effectively sterilizing the food bolus. HCl is so strong that it would burn our skin and clothing, if spilled. However, a thick coating of mucus (mucopolysaccharides) protects the stomach and keeps the acid from burning through its lining. Prostaglandins, small chemical messengers, help keep the mucus layer active by sending messages to replace and repair the stomach lining and provide a protective coating. When this mucus layer breaks down, HCl burns a hole in the stomach lining, causing a gastric ulcer.

Stomach acid also provides our first defense against food poisoning, *Helicobacter pylori*, and parasitic and other infections. Low levels of stomach acid, hypochlorhydria, have been associated with common health issues, including food poisoning, small intestinal bacterial overgrowth (SIBO), and small intestinal fungal overgrowth (SIFO). Stomach acid is also necessary for absorption of many minerals, so mineral depletion may occur with hypochlorhydria.

A normal stomach acid level is a pH of 1.5–2.5. As we age, the parietal cells in the stomach lining produce less hydrochloric acid [3]. Use of acid-blocking medications increases stomach pH to 3.5 or higher, decreasing mineral absorption and opening us up to opportunistic infection.

The stomach also makes pepsin, a protein-splitting enzyme, that cuts the bonds between specific amino acids and breaks them down into short chains of just 4–12. The stomach also produces small amounts of lipase, enzymes that digest fat. Most foods are digested and absorbed farther down the gastrointestinal tract, but alcohol, water, and certain salts are absorbed directly from the stomach into the bloodstream.

23.5 Functional Laboratory Testing

- Heidelberg capsule test. This test is typically performed in an integrative medicine clinic.
- Smart pill: This is typically performed by a gastroenterologist.
- Empiric testing: Utilize betaine HCl supplementation to see if it resolves symptoms (see below).

23.5.1 Key Dietary and Lifestyle Recommendations to Raise Gastric Acid

Betaine HCl Begin with one capsule of betaine HCl with a protein-containing meal. Most people will respond with discomfort, burning, or warmth in their belly. Any sign of discomfort indicates that there is sufficient acid already. Stop the experiment by neutralizing the acid with 1 tsp of baking soda in water or milk. For people who experience no discomfort, titrate the dosage up slowly to a maximum of 2500 mg of betaine HCl per protein-containing meal. Any sign of discomfort indicates too much acid, so you cut the dosage. If symptoms resolve, this supplement can be continued. If symptoms do not resolve, stop. Betaine HCl is an acid and can create an ulcer, if used improperly.

Umeboshi plum Umeboshi plums/apricots are a traditional condiment used throughout Japan, Korea, and China for their health benefits, which include improvements in periodontal disease, improved motility, and inhibition of *H. pylori*. The ume plum is picked unripe, dried in the sun, and then pickled in a brine of sea salt and shiso leaves. The net result is a highly alkaline, naturally fermented pickle that is rich in enzymes and probiotics and has high antioxidant and antibiotic properties. It has been used traditionally for hangovers, liver support, detoxification, nausea, bad breath, dysentery, typhoid, paratyphoid, appetite stimulant, and skin diseases such as eczema [4–8].

Umeboshi plums can be eaten in many ways. They are used as a condiment on vegetables or rice. Plums are very salty but can be eaten whole from the jar. Umeboshi vinegars are also available for use in salad dressings or on rice or other grains. One can also take whole plums or umeboshi paste and drink as a tea. Just let it steep in boiled water for 5 minutes and then drink. This is a very restorative tonic.

Increase acidity with diluted vinegar Dilute 1 teaspoon of vinegar in 10 teaspoons of water and drink with each meal. Gradually increase the amount of vinegar, up to 10 teaspoons. If you experience burning, immediately neutralize the acid by drinking a glass of milk or taking a teaspoon of baking soda in water.

Swedish bitters Bitters are a long-standing remedy for poor digestion in Europe. Combinations of herbs such as gentian, ginger, cinnamon, cardamom, and others stimulate production of HCl and bile, act as antimicrobials, and increase motility. Take bitters either in tablet or liquid form as needed.

Change your eating habits and reduce stress Chew food thoroughly and eat small meals frequently. Small meals are easier to digest. Avoid drinking liquids with meals because fluids dilute stomach acid. Regularly practice stress management by decluttering your calendar, meditating, receiving acupuncture or massage, or doing tai chi or qigong.

23.6 The GALT and the MALT

Throughout our digestive systems, we have immune tissue called gut-associated lymphoid tissue (GALT) and, in the mucosal lining of the digestive lumen, the mucosal-associated lymphoid tissue (MALT). The MALT also encompasses your nose, bronchia, and, in women, the vulvovaginal areas. Altogether, 70% of your immune system lies within the GALT and digestive MALT, which protect us from antigens and other foreign invaders. The tonsils, appendix, and the Peyer's patches within the small intestine are examples of GALT.

Secretory IgA (sIgA) is the primary way that the MALT conveys the message of immune assault. Secretory IgA are antibodies – sentinels on constant alert for foreign substances present in the gut mucosa. When challenged by foreign molecules, sIgA forms immune complexes with allergens and microbes [4, 5, 9]. Immune complexes are clumps of IgA or IgG antibodies that signal the immune system to respond. If these immune complexes get deposited in organs, they can cause disease themselves. Some IgA-associated diseases are IgA nephropathy, vasculitis, lupus, rheumatoid arthritis, scleroderma, and Sjogren's syndrome. Immune complexes signal cytokines to begin the inflammatory process designed to rid our bodies of antigenic materials, a response of the adaptive immune system. Without sufficient sIgA, the MALT cannot work properly [5, 6, 10].

Secretory IgA response is the initial protective antibody which comprises 80% of those in the gut. It is a protective "scout" that signals trouble. Deficiency of sIgA is the most common immunodeficiency. IgA can be assessed in serum and stool. Low levels of sIgA make us more susceptible to infection and may be a fundamental cause of asthma, autoimmune diseases, candidiasis, celiac disease, chronic infections, food allergies, and more. In other words, if the sentry isn't standing at the gate, anyone can come in!

23.6.1 Key Dietary and Lifestyle Recommendations to Raise IgA

Rest and relaxation Ask your clients to rest for 2 hours during daylight every day. Typically, within a few weeks, they are beginning to feel amazingly better.

23.6.1.1 Dietary Supplementation Recommendations

These are suggestions to consider, but avoid if an individual is sensitive or allergic to a product.

- *Saccharomyces boulardii*. Typical dosage 250 mg three times daily [6–8, 11, 12].
- *Vitamin A*. Typical dosage 5000 IU daily. It is recommended to obtain a baseline *vitamin A retinol* blood level before beginning vitamin A retinyl palmitate supplementation to ensure it is indicated for an individual. Avoid recommending dosages of retinol if a person already has a high-end or elevated vitamin A retinol, because vitamin A supplementation above 10,000 IU daily can be toxic; monitor serum retinol (vitamin A) levels every 2–3 months when supplementing.
- *Bovine colostrum:* Typical dosage 500–2000 mg daily.
- *Transfer factor:* Dosage 12.5–75 mg.
- *Medium chain triglycerides (MCT oil)*: Typical dosage up to 2 tbsp. Daily. MCT oil is available as C8, C8–C10, oil, and powder; or eat coconut or drink coconut milk or fresh coconut juice [8, 9, 13].

23.6.2 Key Dietary and Lifestyle Recommendations to Break Down Immune Complexes

23.6.2.1 Dietary Supplementation Recommendations

These are suggestions to consider, but avoid if an individual is sensitive or allergic to a product.

Proteolytic enzymes are taken between meals to increase absorption to assist autophagy processes to break down the blood-clotting enzyme, fibrin, decreasing hypercoagulation, and cleaning up cell debris. Protease enzymes taken between meals can lessen food reactions and decrease systemic inflammation.

- *Porcine proteolytic enzymes*: Contain chymotrypsin and trypsin along with other combinations of proteolytic enzymes
- *Vegan proteolytic enzymes*: Most commonly contain vegan sources of bromelain (pineapple) and papain (papaya), along with other enzymes combinations
- *Nattokinase enzyme:* Speeds up biochemical reactions; extracted from fermented soybeans with a bacterium *Bacillus natto*. Used commonly for cardiovascular heart and circulatory system diseases at 540 FU (fibrinolytic units) dosage providing the ability to break down the blood-clotting enzyme fibrin
- *Boluoke and lumbrokinase* oral enzymes: Derived from earthworms; fibrin-dissolving enzyme used commonly for heart disease and hypercoagulation of cancer, as well as general inflammation

23.7 Small Intestine

The small intestine is hardly small. If this coiled-up garden hose were stretched out, it would average 15–20 feet long. If spread flat, it would cover a surface the size of a tennis court. In the small intestine, food is completely digested and nutrients are absorbed through cells called "enterocytes." The enterocytes are covered with hundreds of small fingerlike folds called villi, which in turn are covered by millions of microvilli. Think of them as small loops on a velvety towel that then have smaller threads projecting from them. The enterocyte layer is only one cell layer thick, but it performs multiple functions of producing digestive enzymes, absorbing nutrients, and blocking absorption of substances that are not useful to the body. The enterocytes are coated with a mucous layer called the "biofilm."

The enterocyte lining is semipermeable. The spaces between the cells are called "tight junctions" and are regulated by occludens and zonulin. Absorption of nutrients and substances into the bloodstream typically occurs through each cell; some occurs between the tight junctions. Zonulin is a molecule that opens the gates between the tight junctions. To date, there are two known activators of zonulin: gluten-containing grains in people who have celiac disease and lipopolysaccharides from gram-negative bacteria (LPS). High levels of zonulin have been reported in autoimmune disease, lung conditions, cancers, and neurological conditions such as multiple sclerosis and schizophrenia [14–16]. When you have high levels of LPS, it is called "endotoxemia." LPS particles are released from mostly gram-negative bacteria as they die and go into circulation, binding to TLR-4 receptors on muscles and organs. This triggers inflammatory molecules such as IL-6 and inflammatory cytokines, ultimately damaging tissue. Elevated LPS has also been associated with changes in tryptophan metabolism, increasing quinolinic acid, kynurenine, cortisol, and inflammation with simultaneous decreases in insulin sensitivity, thyroid function, melatonin, and glutathione.

The intestinal lining repairs and replaces itself every 3–5 days. The intestinal lining has a paradoxical function: it allows nutrients to pass into the bloodstream while blocking the absorption of foreign substances found in chemicals, bacterial products, and other large molecules found in food. If maintenance is delayed due to stress, injury, infection, toxic exposure, medications (such as antibiotics steroids, oral contraceptives), or illness, there will be increased intestinal permeability, also called "leaky gut." When this occurs, large molecules such as toxins, microbes, chemicals, and molecules from food enter the bloodstream, triggering an immune system reaction (Fig. 23.1).

Leaky gut syndrome puts an extra burden on the liver. All foods pass directly from the bloodstream through the liver for filtration. The liver "humanizes" the food and either lets it pass or changes it, breaking down or storing all toxic or foreign substances. Water-soluble toxins are easily excreted, but the breakdown of fat-soluble toxins is a two-stage process that requires energy. When the liver is bombarded by inflammatory irritants from incomplete digestion, it has less energy to neutralize chemical substances. When overwhelmed, the liver stores toxins in fat cells to deal with later. If the liver has time later, it can deal with the stored toxins, but most commonly it is busy processing what is newly coming in and never catches up. These toxins provide a continued source of inflammation to the body. Increased intestinal permeability is the driving factor in liver diseases, such as cirrhosis and nonalcoholic fatty liver disease (NAFLD) [29–32].

Stop the mediators that perpetuate the problem:

- *Excess stress.* Create the space in your life to relax and renew every day. Nap; meditate; do abdominal breathing exercises, tai chi, qigong, or a hobby; or watch birds in your yard. You choose, but do choose.
- *Poor sleep.* Your body needs 7–9 hours of sleep each night. When healing, often more. Go to bed early enough to achieve this. It is hard to heal when you are sleep-deprived.
- *Pain medications* that injure GI lining, such as nonsteroidal anti-inflammatories (NSAID), i.e., ibuprofen and aspirin.
- *Use of birth control pills, steroid medications.*
- *Environmental contaminants.*

Increased Intestinal Permeability Associated with Many Health Conditions

Acute pancreatitis	Chronic Fatigue Syndrome	Kidney Stones
Asthma	Eczema	Migraines
Autism	Food Intolerances	Multi-Organ Failure
Autoimmune hepatitis	Fibromyalgia	Multiple sclerosis
Autoimmune disease	IgA nephropathy	Non-Alcoholic Liver Disease
Bechet's disease	Inflammatory bowel diseases	Primary biliary cirrhosis
Burn patients	Irritable Bowel Syndrome	Primary sclerosing cholangitis
Celiac Disease		Psoriasis

Fig. 23.1 Increased intestinal permeability associated with many health conditions. (Based on data from Refs. [14, 17–28])

- *Overconsumption of alcohol.*
- *Poor food choices.*
- *Treat infection.*

Diet:
- Avoid foods that you are sensitive to.
- Eat gut-healing foods. Homemade chicken stock, beef stock, and fish stocks are inexpensive and contain nutrients, such as gelatin, glucosamine, and chondroitin, that help heal leaky gut better than anything else. It's a food, so consume to taste.

Supplements: Can be found individually or in combination products.
- L-glutamine (glutamine): Dosages vary 1–30 g daily. Begin with 1–3 g daily. Heat destroys its properties, so take with cold or cool beverage. Best on empty stomach. Many people find that glutamine enhances their muscle endurance, which is a lovely side benefit. Too much glutamine can be constipating, so use that as an indicator. Occasionally glutamine makes someone feel wired or anxious. If so, stop taking it; it is not for you. If you have kidney disease, be cautious in taking more than 1–3 g daily. Caution when recommending glutamine for oncology patients, especially later-stage progression as some cancers use glutamine as a fuel, along with glucose [33, 34].
- Zinc or zinc carnosine: Typical dose 75 mg of zinc carnosine twice daily (totals 34 mg of zinc) or 25–50 mg of other type of zinc.
- Aloe vera. Dosage varies. If utilizing fresh aloe, use one to two pieces the size of a thumb. Peel and utilize only the inside pulp.
- Colostrum: 1000–3000 mg daily.
- Probiotics. *Lactobacillus plantarum* is specifically soothing to the small intestine. Take 1 daily.
- Quercetin. Dosage: 500–3000 mg daily.
- Digestive enzymes with meals

Optional supplements:
- Gamma oryzanol. Dosage 100 mg three times daily
- Fish peptides. Brand: Seacure. Six capsules daily in divided doses. Keep in freezer to make it more palatable.
- Vitamin A. 5000 IU of preformed vitamin A: retinol. Do not take >5000 IU if you are pregnant or planning to become pregnant. Best to test vitamin A retinol status before determining need for supplementation.
- Increase antioxidants. Vitamin C: dosage 500–10,000 mg daily, and/or a full-spectrum antioxidant supplement.
- Deglycyrrhized licorice. Dosage two tablets between meals as needed, up to four times daily.
- Phosphatidylcholine. 2000–4000 mg daily.
- Herbal blends with combinations of marshmallow root, slippery elm, arabinogalactan, ashwagandha, ginger, MSM, etc. usually powdered or capsules.

23.8 The Gut Microbiota

One of the newest discoveries in the digestive system is the microbiome. Each of us has 2–7 pounds of microbes in our digestive system, about the size of the brain or liver. While these live throughout the entire digestive tract from the mouth to the anus, the great majority live in the colon and large intestine.

These microbes are comprised of bacteria, beneficial viruses known as bacteriophages or phage, fungi, archaea, and parasites that constitute more than 99% of the DNA in the human body [35]. This is a complex community that functions to stabilize overall health and keep us robust. We have as many bacteria in our microbiome as cells in our body [36]. Viruses equal or outnumber bacteria in the microbiome and regulate cell signaling of interferons and cytokines [37, 38]. The mycobiome are the fungi in our microbiome; they have not been well-studied as of this writing. *Saccharomyces boulardii* is the best-studied of the beneficial fungi. It is typically used as a prebiotic and to treat diarrhea from all causes [39–43]. Current research suggests that imbalances in this "organ" enhance nutrient absorption; synthesize vitamins; and drive obesity, type 2 diabetes, nonalcoholic fatty liver disease, mental health issues, drug and toxin metabolism, and intolerance to pain (Fig. 23.2).

23.9 The Microbiome: Bacteria

Of microbes, there are many families and phyla, with the phyla *Bacteroidetes* and *Firmicutes* predominant. These families are comprised of hundreds of subfamilies and types of bacteria. No matter their names, they fall into three categories: symbiotic bacteria, commensals, and pathogens. Symbiotic bacteria provide a benefit to the host, such as *Lactobacilli* and *Bifidobacterium* species. When used in supplemental form, we call these symbiotic microbes "probiotics." Commensals enhance digestion of fats, proteins, and carbohydrates and synthesis of SCFA and vitamins. They also aid detoxification and protect us from pathogenic microbes [44]. As more is learned about the specific roles of each commensal, many will be recategorized as symbiotic. Pathogens, which have gathered the most attention because of their devastating effects, comprise a smaller group of disease-causing microbes. In a healthy human gut, these live in balanced communities. When out of balance, we call this "dysbiosis," which is a general disordered microbiome rather than an infection with a specific pathogen.

In the digestive system alone, you have many different microbiomes. For example, your gingiva, tonsils, tongue, teeth, and saliva each have their own microbiomes. If you kiss someone, do you collect some of their microbiota? Research indicates you receive 80 million bacteria for every 10 second kiss [45]!

The microbiome begins to develop in the womb and matures during the first 3 years of life. Research indicates that this development is associated with how well our immune system and metabolism function. This process can be

The Microbiome in Health & Disease

IN HEALTH	OUT OF BALANCE / DYSBIOSIS
• Digestive Health: motility, function, digestion • Drug Metabolism • Heavy Metal Detoxification • Increased nutrient absorption: fats, protein, minerals • Metabolism • Modulate Immunity /Inhibit Pathogens • Overall Health • Production of Short-Chain-Fatty Acids (SCFA) • Synthesis of vitamins: biotin, folate, B1, B2, B3, B6, B12, and K.	• Atopic Illness • Autoimmune Disease • Cancers • Cardiovascular disease • Chronic kidney disease • Dermatological issues • Diabetes • Digestive Conditions • Heart Failure • Liver diseases • Mental Health: Depression, Schizophrenia, Anxiety, Autism, ADHD • Obesity • Pain Tolerance • Sleep disruption

Fig. 23.2 The microbiome in health and disease

enhanced with vaginal delivery and breastfeeding, having a furry pet in the home [46], playing outdoors in dirt, and having older siblings. This development may be hampered by birth by C-section, bottle-feeding, antibiotics, and use of other medications [47–49] (Fig. 23.3).

23.10 Biofilm Layer

The gut microbes live in communities called biofilms. The biofilm layer contains antibacterial proteins and acts as a protective barrier for the microbial communities, protecting the gut lumen. Mucin proteins contain glycosylated carbohydrates that are used as fuel by commensal and symbiotic microbes, converting them into SCFA, which provide energy for the enterocytes.

When the microbial communities are out of balance, infection can set in the biofilm layer and also in the epithelium to which they adhere. Commensal and pathogenic microbes typically stay inside the gut lumen, yet this is an imperfect system and some continuously make their way into the gut-associated lymphatic tissue (GALT), triggering an immune and inflammatory response.

Although we have no real research on protection of the biofilm layer, gut-soothing foods and herbs have been used traditionally to enhance mucus production and soothe the gut. In herbal medicine, these are called "demulcents." These include licorice, slippery elm, marshmallow root (*Althaea officinalis*), fenugreek tea, figs, almonds, oats, and okra. Utilizing a gut-healing therapeutic dietary approach will also be of benefit. (See later section in this chapter.)

23.11 Healing the Gut: The 5R Protocol

The 5R protocol is widely utilized in integrative and functional medicine.

- *Remove*: Remove stressors such as infection, toxins, foods that provoke reactions, processed foods, refined sugars, nonessential medications, and molds.
- *Replace:* Enhance digestion by utilizing digestive enzymes, betaine hydrochloride, and bile salts when needed. Replace an inflammatory Western diet with a whole-food diet or gut-healing therapeutic dietary plan.
- *Reinoculate:* Eat probiotic- and prebiotic-rich foods. Take probiotic and/or prebiotic supplements containing immune-regulating species such as *L. acidophilus*, *L. reuteri*, *Bifidobacterium*, *Streptococcus thermophilus*, and *Bacilli* species.
- *Repair:* Eat gut-healing foods such as bone stock and vegetable broths. Eat at least nine servings (4.5 cups) daily of vegetables and fruit. Polyphenols and plant bioactives regulate inflammatory mediators. Increase dietary intake of gut-healing nutrients such as zinc, L-glutamine, vitamin A, and omega-3 fatty acids. Utilize nutritional supplementation as discussed for increased intestinal permeability: aloe vera, quercetin, colostrum, etc.
- *Rebalance:* When someone is ill and improves, they will come to a "new normal" which may be healthier or less robust than before becoming ill. This may affect positively or negatively what one can achieve in a day, week, or year and will require adjustment. Examine lifestyle issues, such as sleep, exercise, and stress management.

23.12 Role of Nutrition in Balancing the Gut-Immune System: Therapeutic Diets

Research also indicates that changing what we eat has the greatest impact on our microbiome [50, 51]. Food can have both inflammatory and healing effects. In your initial assessment, you will look for macronutrient, micronutrient, fiber, and hydration adequacy through a food diary and any available clinical assessments. If someone is fatty acid- or protein-insufficient, digestion and absorption will not be optimized.

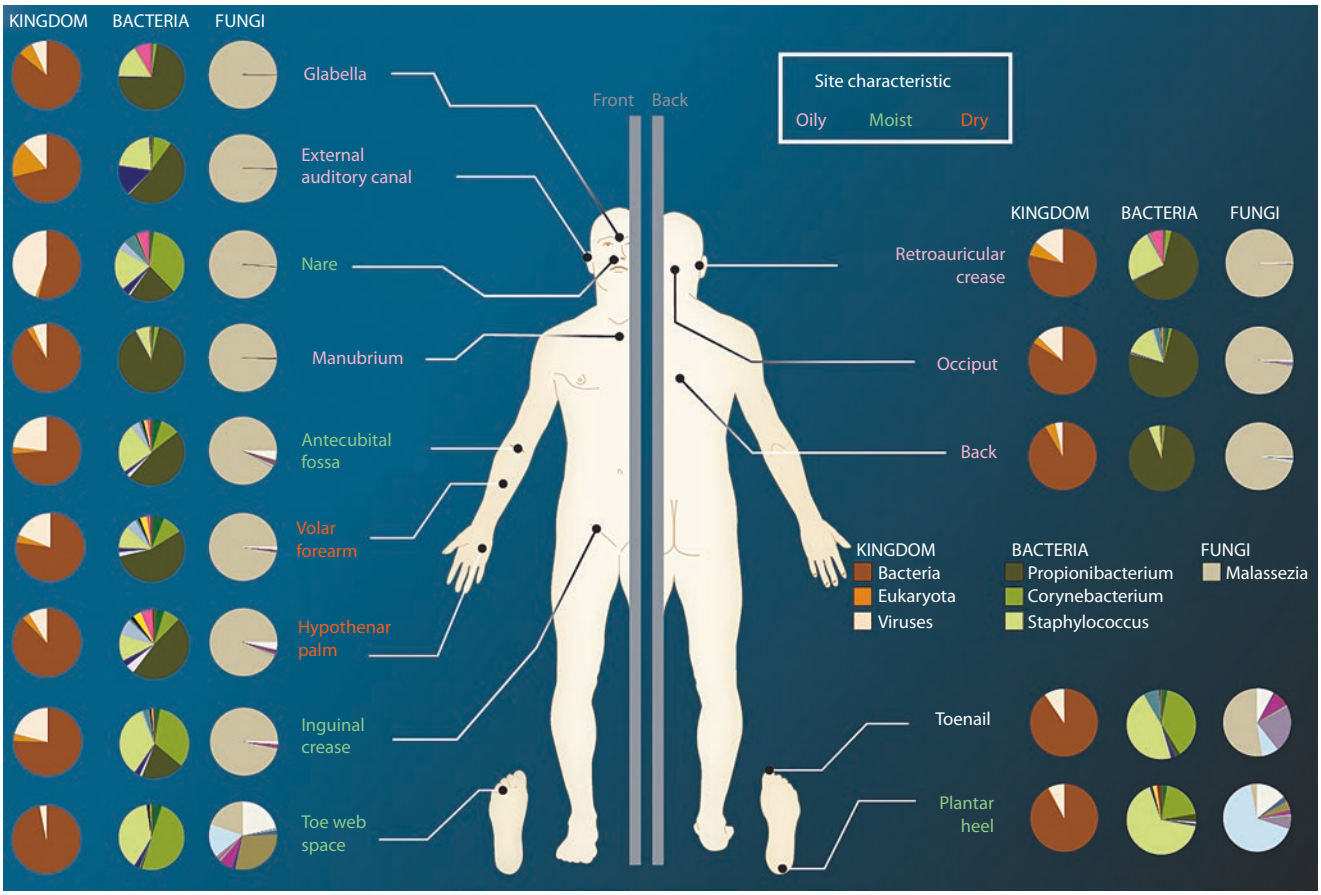

Fig. 23.3 Microbiome sites: the microbiota composition of each tissue is unique. (Reprinted from: ► https://commons.wikimedia.org/wiki/File:Microbiome_Sites_(27058471125).jpg. With permission from Creative Commons Attribution: ► https://creativecommons.org/licenses/by/2.0/)

Recommendation of an anti-inflammatory, low-antigenic food plan can decrease inflammation better than medications. The standard Western diet is inflammatory, so begin with a whole-food, low-processed elimination diet protocol. Utilizing a therapeutic elimination diet is simple: Avoid foods that potentially cause inflammation and eat only foods that have a low possibility of provoking a reaction. This is a therapeutic approach and used for a minimum of 2 weeks to a maximum of 3 months with a reintroduction phase to determine which foods provoke reactivation of symptoms. In some cases, some people may need to stay on a modified therapeutic dietary program for up to 2 years until the gut heals completely. Often the foods people react to are the ones that we least want to live without. If a patient says "I just couldn't live without dairy," dairy may be that patient's problem food. The food groups with the most common reactions include refined sugar of all types, gluten-containing grains, dairy products, soy-containing foods, and eggs.

There are many types of elimination diets. What they have in common is that they are based in whole foods and have the effect of enhancing digestion and absorption, reducing inflammation, helping to balance the microbiome, increasing intestinal permeability, and reducing toxic burden. Many also restrict carbohydrates. The best studies and most frequently utilized approaches include the comprehensive elimination diet, FODMAP diet, and the specific carbohydrate diet. Although prebiotic, probiotic, and high-fiber foods are health-promoting when we are healthy, these foods feed the microbial imbalance when we have dysbiosis. Therefore, avoiding them for a period of time helps starve out the problematic microbes. These are therapeutic diets and not meant to become a lifestyle. It's important to heal the other underlying factors, so that people can begin eating more normally again. One caution, is that these diets can feed into disordered eating patterns. So, good counseling about their temporary nature is important. Diet, along with herbal or pharmaceutical treatment for dysbiosis, and healing permeability, provides a synergistic approach for healing.

For people in whom inflammation, pain, and/or mental health issues dominate, try a comprehensive elimination diet. For people with dysbiosis or those who feel worse eating any carbohydrates, eating a low-carbohydrate, low-starch diet works best. Examples of this include the candida diet, body ecology diet, and the gut and psychology syndrome diet (GAPS), although currently we have no published research on the benefits.

While many foods may be unmasked during the elimination/provocation challenge, others may remain hidden. To enhance this process, you may also want to have a blood test for food sensitivities, allergies, and intolerances. Looking at antibodies is examining the adaptive/acquired immune sys-

tem. IgG, IgG4, IgA, and IgM tests report on food sensitivities, although IgG or IgG4 are most common. IgE testing reports on true allergic reactions. Testing for lactose, fructose, and celiac disease reports on enzymatic insufficiencies. Tests such as the MRT-LEAP and ALCAT tests report on the adaptive immune process. There is no standardization of food sensitivity testing; yet, any of these tests can be clinically useful by lowering the threshold of activation.

Sensitivities are rated from normal to severe reactions. In addition to a detailed readout documenting individualized reactions, most laboratories also include a list of foods which contain hidden sources of the offending foods, a rotation menu, and other educational material to help patients in the healing process.

23.13 Prebiotics and Benefits

Prebiotics are food for the microbes of the microbiome. The average person today eats few prebiotic-rich foods, although historically we ate many. The definition of a prebiotic is: "A substrate that is selectively utilized by host microorganisms conferring a health benefit" [52]. In other words, prebiotics are food for the symbiotic and commensal microorganisms of the microbiome. Typically, they are "eaten" by the microbes which activates the bioactive food components. They contribute to colon health by synthesizing short-chain fatty acids: butyrate, valerate, and propionate. Prebiotics have been reported to have many benefits (Fig. 23.4). Some diets, such as the low-FODMAP diet, temporarily restrict many prebiotic-rich foods.

Breast milk is a rich source of prebiotics and helps to establish the infant microbiome. Common prebiotic foods include kitchen herbs and spices, legumes, pulses, jicama, Jerusalem artichoke, onions, chicory, garlic, leeks, plantain, unripe bananas, fruit, burdock root, asparagus, radishes, dandelion root, peas, honey, green tea, black tea, cultured dairy products, artichoke, tomatoes, beets, and whole grains such as rye, barley, and sprouted wheat.

23.14 Selected Therapeutic Foods

Kefir: Supports immune health with a variety of prebiotics and probiotic microbes. Research reports that it supports gut-immune health, improves lactose digestion, has cancer-protective properties, and has been used to heal peptic and duodenal ulcers [55]. Kefir can be made from animal milk (cow, goat, sheep, buffalo, yak) or nondairy liquids such as water, nut milk, or seed milk.

Kimchi: Reported to help regulate bowel movements, improve metabolism and weight, reduce high-serum cholesterol levels, provide anticancer nutrients, promote immune and brain health, and reduce fibrinogen levels [56].

Ginger: Ginger has been reported in many papers to be effective for digestive conditions including colic, nausea, appetite stimulation, and digestion enhancement. It is used as a prokinetic to enhance motility in small intestinal bacterial and fungal overgrowth [57–59].

Cabbage juice: Research reports that cabbage juice is an effective immune modulator of peptic ulcers, diabetes, cirrhosis, arthritis, and cancers [60]. It has also been reported to enhance motility and gastric secretion. It contains the nutrients glutamine, methionine, and sulforaphanes. The dosage utilized was a quart of fresh cabbage juice daily for 7–10 days in divided disease. The taste is not pleasant, so diluting it with cherry or pomegranate or other juice may be beneficial for compliance. It is also effective as a dried powder in capsules [61–67].

23.15 Therapeutic Role of Probiotic Supplements

The definition of a probiotic is: "live microorganisms that, when administered in adequate amounts, confer a health benefit on the host" [68]. Probiotics from food and supplements modulate immune and inflammatory responses. Probiotics also improve lactose tolerance, enhance metabolism, regulate serum lipids, enhance digestive function,

Prebiotic Benefits

• Improved bowel function • Promote growth of Bifidobacteria, • Lactobacilli and other beneficial microbes • Colon pH • Protect against negative effects of bile acids • Substrate for SCFA • Improves intestinal permeability • Improved Metabolism of microbiota • Adds sweetness to food • > Satiety • Stimulates neurochemical production in the gut	• > bone density (+ calcium) • > serum cholesterol and triglycerides • Cancer protective • Used in treatment of atherosclerosis • Immune function • Neural and cognitive function • Skin • > insulin sensitivity & glucose regulation (in all and Type 2 DM) • > mineral absorption • Small but sig. effects body weight

Fig. 23.4 Prebiotic benefits. (Based on data from Refs. [52–54])

help control inflammatory bowel disease and irritable bowel syndrome, improve innate immunity, inhibit infection, and balance the microbiome [69]. Probiotic supplementation has demonstrated benefits in virtually all health conditions. They have been shown to be of benefit in digestive and immune conditions including celiac disease, parasitic infection, *H. pylori* infection, inflammatory bowel disease, bariatric surgery, irritable bowel syndrome, cardiometabolic syndrome, allergy, lupus erythematosus, rheumatoid arthritis, and lower serum cortisol levels. They can also help protect from a variety of cancers. What is less exactly known is what strains, dosages, and timing of specific probiotics to use in specific people at a specific moment in time. Dosages range from millions of colony-forming units (CFU) daily to trillions of CFU of supplemental probiotics daily.

23.16 Conclusion

The gut-immune system is an enormous topic; this chapter looks at some key points in a concise manner and provides clinical pearls to direct the nutrition care process. Research in the area of the gut-immune system, its relationship to systemic balance and disease, and the role of food, nutrition, and lifestyle is ballooning exponentially and will continue to evolve. Common themes for balancing the gut-immune system include stress management, increases in dietary polyphenols and plant bioactive components, use of digestive healing therapeutic dietary approaches, and inclusion of probiotic- and prebiotic-rich foods and supplements to modulate immune expression and promote health. Of critical importance is optimizing barrier function of the enterocytes to prevent and reduce immune and inflammatory responses. Diet and lifestyle play a major role in maintaining gut-immune health. Utilizing integrative and functional approaches promotes health maintenance and helps restore function throughout the body.

"All disease begins in the gut." This quote is frequently attributed to the ancient Greek physician Hippocrates nearly 2500 years ago. Traditional medical systems acknowledged the primacy of the gut as many remedies for systemic disorders involved purgatives to expel toxins and pernicious humors.

With the Scientific Revolution, the emergence of a rationalistic model ushered in insights about the process of digestion and nutrient assimilation. This resulted in a more reductionist model of the "alimentary canal" as a food tube with little function except as a mere conduit for nutrients and waste products (see Fig. 24.1).

Nevertheless, the early twentieth century saw a reinstatement of a more global appreciation of the role the GI tract plays in overall physical and mental well-being [1, 2].

The pioneering work of Eli Metchnikoff highlighted the involvement of intestinal microbes in promoting or attenuating "autointoxication." This was accompanied by popular reform movements, such as that of John Harvey Kellogg calling for enemas, fiber, and fasting to avert "toxemia." Radical surgeons even proposed colectomies to abrogate the "autointoxication" that was a presumed cause of "melancholia." [3]

The pendulum soon swung back with a firm repudiation of intestinal toxicity as an imaginary hypothesis. In 1912, famed pediatric surgeon Hastings Gilford stated that "autointoxication, the term as we commonly use it, is significant of nothing but a sort of mental flatulency on the part of the user as a substitute for thought." [4]

Consequently, investigation of the role of the GI tract as a determinant of overall health was kept in abeyance for much of the twentieth century, until a recent resurgence of interest in the microbiome led to a greater appreciation of its role in mediating metabolism, immunity, brain health, and endocrine function.

Microbiota lie within the anatomical gut. They consist of communities of bacteria, fungi, and viruses. Rather than being casual colonizers, the constituents of the microbiome elaborate essential nutrients, provide immunological signaling, perform detoxifying functions, influence metabolism, and influence neurotransmitters and hormones (see Fig. 24.2).

The essentiality of intestinal flora that makes up the microbiome has been underscored by experiments in which germ-free animals encounter numerous liabilities. The composition of the microbiome is, to some extent, genetically programmed; its proper acquisition is encouraged by inoculation via vaginal birth and supported by humoral factors secreted in breast milk. Western lifestyle is thought to pose serious challenges to the integrity of the microbiome (see Table 24.1, "Factors that undermine the microbiome").

To turn the conventional paradigm on its head, the GI tract is not merely a conduit for feces, but rather a carefully engineered housing for the microbiome, which itself may well deserve the status of an organ, with multiple functions.

24.1 Impact of the GI Tract on Immunity

The intestinal microbiota are important constituents of the human immune system and are essential for protection against pathogens. Evidence supporting this comes from studies showing that animals bred to be germ-free are highly susceptible to infection. The presence of commensal microbes provides necessary stimulation to the intestinal immune system which, via structures like Peyer's patches, regulates local and systemic immune responses via the elaboration of immunoglobulins [5].

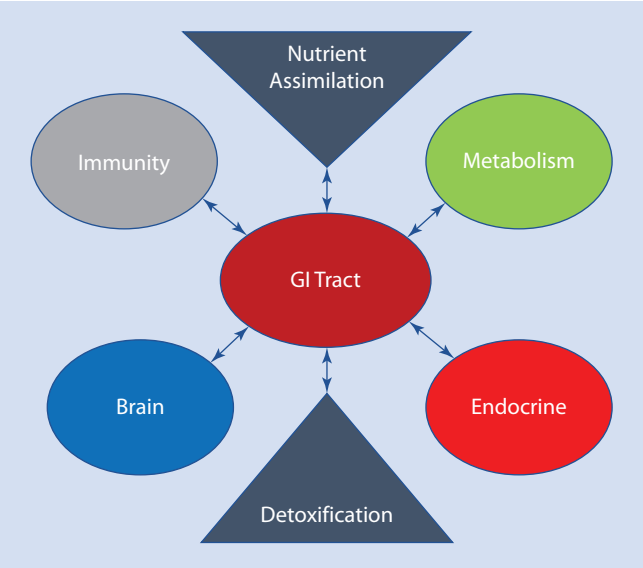

Fig. 24.2 Broader understanding of the GI tract's bidirectional systemic relationships

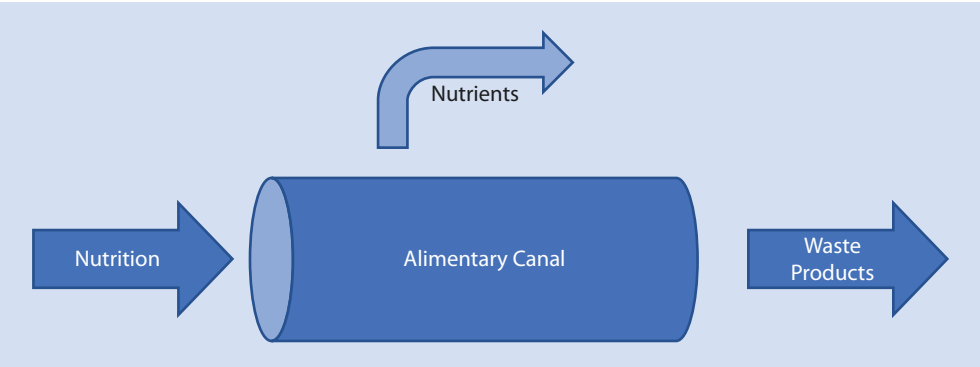
Fig. 24.1 Mechanistic model of GI tract



Clinical studies in humans suggest a robust effect of probiotic supplementation on infectious disease susceptibility. Frequency and duration of upper respiratory infections were reduced with oral probiotic administration [6].

It has also been demonstrated that human microbial dysbiosis is associated with production of pathogenic cytokines, which suggests a causative role in inflammatory and autoimmune disorders [7]. Researchers revealed that the presence of filamentous bacteria in young mice with an engineered predisposition to autoimmunity caused spontaneous generation of antibodies to cell nuclei – a feature of autoimmune disorders like lupus and systemic sclerosis [8]. Multiple sclerosis patients were found to have reduced levels of good bacteria ordinarily derived from diets high in healthy fiber [9]. Children with MS had different intestinal bacteria than those without MS [10].

24.2 GI Impact on the Brain

The gut-brain connection is now the subject of intense investigation. A well-acknowledged example of the impact of the GI tract on brain function is the phenomenon of hepatic encephalopathy in patients with advanced liver cirrhosis. Asterixis and delirium are relieved by administration of an osmotic laxative (lactulose) and luminally active antibiotics (neomycin and more recently rifaximin). Lately, probiotics have been shown to prevent hepatic encephalopathy in cirrhotics [11].

Speculation has arisen over the relationship between dysbiosis and neurodevelopmental disorders like autism. It has been demonstrated that children with autism have different bacteria and that their microbiota may modulate behavioral and physiological abnormalities [12]. While psychological stress has been found to alter the microbiome, the authors conclude that bacterial anomalies are the cause, not the consequence of, behavioral disorders [13].

Additional evidence has been adduced for the role of the microbiome in Parkinson's disease, Alzheimer's disease, depression, and anxiety. In fact, clinical trials of probiotic administration have been demonstrated to impact mood [14].

Table 24.1 Factors that undermine the microbiome

Antibiotics, antimicrobials (intentionally administered or from food or water)	Artificial sweeteners
Chlorinated, fluoridated water	Drugs (PPIs, H2 blockers)
C-section	Stress
Lack of breastfeeding	Sedentary lifestyle
Refined carbohydrates	Western hygiene
Inadequate fiber and polyphenols	GMOs?
Chemicalized food (e.g., emulsifiers)	

24.3 GI Endocrine Effects

The GI tract influences endocrine function in many ways. The systemic immune dysregulation that underlies celiac disease—and even non-celiac gluten sensitivity—has been shown to be associated with thyroid autoimmunity, with consequent hypothyroidism [15]. In a reciprocal fashion, the intestinal stasis that is sometimes a feature of hypothyroidism has been demonstrated to reinforce small intestinal bacterial overgrowth (SIBO), perpetuating a vicious cycle wherein dysbiosis generates pathological cytokines that promote thyroid autoimmunity.

Bacterial action is, in part, responsible for conjugation and enterohepatic processing of endogenous sex hormones and xenobiotics (sometimes referred to as "gender benders"). Hence, dysbiosis may be linked to such conditions as estrogen dominance, menstrual abnormalities, and reproductive system cancers [16]. The impact of the microbiome may account for the demonstrated ability of oral administration of fiber and especially lignans from flax and other plant sources to attenuate hormone imbalances.

Lipopolysaccharides (LPS) from bacteria have also been shown to inhibit growth hormone (GH), which may help account for the growth retardation seen in children with inflammatory bowel disease—which is sometimes treated with growth hormone injections.

It is even thought that the intestinal microbiome exerts an effect on skeletal fitness via its impact on sex hormones, glucocorticoids, serotonin, PTH, and cytokines [17].

24.4 GI Impact on Metabolism

In a series of remarkable experiments, it was demonstrated that propensity to obesity can be transferred from a fat rodent to a thin rodent via fecal inoculation; the converse also occurs when flora from lean animals are transferred to fat animals [18]. This underscores the notion that disruption of normal intestinal flora (dysbiosis) can predispose to metabolic derangement—even diabetes and associated comorbidities.

There is evidence that the relative balance of two major bacterial phyla within the digestive tract—*Firmicutes* and *Bacteroidetes*—is a determinant of susceptibility to weight gain [19]. This has prompted speculation that the global obesity epidemic is fueled not just by caloric excess and sedentary lifestyle but also by harmful environmental influences on the microbial diversity that characterizes a healthy microbiome.

While this phenomenon has not been definitively confirmed in humans, there are anecdotal accounts of individuals who have received fecal transplants for *Clostridium difficile* infections and became overweight after the donors were not properly screened for obesity [20].

Additionally, while it was once thought that the weight loss in gastric bypass surgery was mechanistically attributable to deliberately induced malabsorption and/or reduced gastric volume, new evidence has emerged that alterations in the GI microbiome may be, at least in part, responsible for altered

metabolic disposition of consumed nutrients. Transfer of gut microbiota from Roux-en-Y-treated mice resulted in weight loss in surgically naive mouse recipients, suggesting a robust effect of microbial alteration on weight [21].

How does the microbiome exert its influence on metabolism? For one, nutrient extraction may be dependent on microbiota composition. For another, byproducts of microbial degradation of nutrients may play a role in signaling complex regulatory pathways, promoting or attenuating appetite and weight gain via insulin, adiponectin, leptin, or intestinal peptides [22]. Additionally, the presence of certain organisms may promote inflammation, an acknowledged contributor to metabolic syndrome [23].

The relationship of the microbiome to metabolism is now the subject of intense research. NIH funds were recently authorized for a study to see if the microbiome is linked to diabetes risk in Hispanic Americans, a population that has seen obesity rates skyrocket secondary to cultural changes [24].

24.5 GERD

For nearly 80 years, it has been unchallenged scientific dogma that heartburn (more recently dubbed gastroesophageal reflux disease or GERD) is a matter of unchecked acid secretion. Tens of millions of Americans have chewed calcium pills, quaffed first-generation acid blockers (Tagamet, Zantac, Pepcid), and now are reliant on even more powerful proton pump inhibitors (PPIs) like Prilosec, Prevacid, Nexium, Aciphex, and Protonix.

But according to a revolutionary new study, we may have been barking up the wrong tree: GERD is now thought to be caused by inflammation, not just hyperacidity. Researchers at the University of Texas Southwestern Medical Center and Dallas VA Medical Center have proven that GERD is actually an inflammatory response prompted by the secretion of proinflammatory cytokines [25].

Researchers "burned" the intestinal linings of mice with acid equivalent to the pH of refluxed gastric juice. They discovered that the resulting damage was not consistent with the typical pathology of GERD. Rather, the acid triggered a slow-developing inflammatory cascade that took weeks to resemble the usual findings of GERD.

This doesn't mean that acid suppression is without value in treating GERD. But it does suggest that targeting inflammation would be a better way of treating and preventing it, especially since long-term PPI use has so many side effects (see ► Box 24.1).

Additionally, many GERD patients obtain only incomplete or partial relief from their antacid drugs. Why should this matter to the estimated 20% of Americans suffering from upper GI pain? While acid blockers offer temporary relief, they don't get to the bottom of the problem. Additionally, chronic use may engender rebound hyperacidity. Therefore millions of Americans remain reliant on them, sometimes for their entire lifetimes.

Box 24.1 Conditions associated with chronic proton pump inhibitor use

- Nutrient deficiencies
- Osteoporosis
- Susceptibility to gastroenteritis and *Clostridium difficile*
- Coronary artery disease/MI
- Stroke
- Dementia
- Pneumonia
- Irritable bowel syndrome
- Nausea, rash, headache

24.6 Diet for GERD

Lifestyle interventions have long been fundamental to management of GERD symptoms. Patients are exhorted to lose weight, per likelihood that intra-abdominal pressure associated with excess girth may prompt reflux. They should eat smaller meals and refrain from eating before recumbency at bedtime. They should elevate the head of their beds, but not simply use extra pillows, which can increase pressure on the abdomen. Tight, constricting clothing should be avoided. Smoking is discouraged. Use of aspirin and NSAIDs, which have an erosive effect on the esophageal lining, is to be minimized.

Traditional GERD diets entail elimination of classic food and beverage precipitants:

1. Acidic foods and beverages like coffee, citrus, tomatoes, and vinegars
2. Carbonated beverages, which induce belching
3. Fried and fatty foods, which delay gastric emptying
4. Spicy food
5. Peppermint candies or gum, which relax the lower esophageal sphincter
6. Alcoholic beverages

But, in clinical practice, these measures often fail to curtail GERD symptoms. The reason may be that some patients have idiosyncratic reactions to specific "innocuous" foods, like dairy, wheat, or eggs. These intolerances are unlikely to be revealed by allergy skin testing or the IgE RAST. Rather, they must be unmasked via elimination and reintroduction.

Additionally, many patients with GERD react to the ubiquitous food additive MSG, often overlooked as a harmless "natural flavoring" in processed foods. MSG provokes gastric acid hypersecretion [26].

A promising avenue for patients unresponsive to the usual diet measures for GERD is the very low-carbohydrate (VLC) diet. In a small sample of patients, the VLC diet demonstrated symptom relief and reduced distal esophageal acid exposure [27]. While the authors claim the mechanism for this improvement is unknown, it is likely that carbohydrate restriction reduces microbial proliferation in the gut, as in IBS.

24.7 Supplements for GERD

DGL (Deglycyrrhizinated Licorice) While DGL has not been formally studied for GERD, studies in the 1980s demonstrated its curative effects in gastritis. While licorice has demonstrable anti-inflammatory effects, it contains a substance, glycyrrhetinic acid, which can cause pseudoaldosteronism, a condition where the body retains sodium, loses potassium, and accumulates fluid volume, sometimes resulting in edema and hypertension.

Melatonin Considerable research validates the benefits of melatonin in GERD. Melatonin [28] is best known as a sleep aid and circadian rhythm regulator. In the body, it is manufactured by the pineal gland, located deep within the brain. Often overlooked is that the gastrointestinal tract contains up to 400 times more melatonin than is secreted by the pineal gland. Research demonstrates that melatonin has the ability to suppress excess acid production. It also shields the GI lining from the destructive effects of free radicals caused by stress, toxic agents, or ulcer-causing drugs like NSAIDs.

A recent study showed that melatonin outperformed famotidine and boosted the effectiveness of omeprazole in alleviating symptoms and preventing tissue damage in patients with GERD [29]. The researchers summarized: "From the results of our study, it can be concluded that melatonin could be used in the treatment of GERD, either alone or in combination with omeprazole. The combination therapy of both melatonin and omeprazole is preferable, as melatonin accelerates the healing effect of omeprazole and therefore shortens the duration of treatment and minimizes its side effects." The suggested dose of melatonin for GERD is 3–6 mg at bedtime.

Mucilaginous Substances Marshmallow, plantain, and apple pectin are mucilaginous substances that soothe the esophageal mucosa; they belong to a category of herbs known for demulcent properties.

Limonene While its method of action is poorly understood and there is a dearth of human clinical studies, d-limonene, a terpene extract of citrus fruit, has been advanced as a potential ameliorant for GERD [30].

Alginate A "raft-forming agent" in the presence of gastric acid, alginate forms a gel. In the presence of bicarbonates added to the formula, alginate forms a pH buffer layer that offers protection to the esophageal mucosa.

STW 5 (Iberogast) A popular German formulation used extensively in Europe for treatment of dyspepsia, Iberogast is a liquid combination of the herbs *Iberis amara*, Angelica, chamomile, caraway fruit, St. Mary's thistle, balm leaves, peppermint leaves, celandine, and licorice root. Together, they exert anti-inflammatory, antibacterial, and pro-motility effects.

The latter makes Iberogast particularly helpful for GERD. By including certain herbal "bitters" that are traditional digestive aids, Iberogast promotes optimal gastric emptying and intestinal transit, alleviating the stuck feeling that many GERD sufferers experience. Due to its dual antibacterial and pro-motility effects, Iberogast is ideal for sufferers of SIBO (small intestinal bacterial overgrowth), a frequent contributor to the reflux and sour eructation of heartburn sufferers.

Aloe Another traditional remedy for gastrointestinal ailments, aloe is most familiar as a home first-aid treatment for burns—hence its application to esophageal inflammation.

For aloe to work best, it is preferable to use the gel form, in generous amounts, away from food. I generally suggest ¼ cup of a purified aloe gel product or fresh aloe juice 3 or 4 times daily away from meals.

In a recent study, aloe syrup was found to be comparable to Zantac and Prilosec in relieving symptoms of GERD and was well tolerated [31].

Probiotics No formal studies have been done on administering probiotics for GERD. But it stands to reason that easing dysbiosis might relieve out-of-control bacterial proliferation which can lead to upper intestinal gas and upward reflux of stomach contents.

Acidify Among the more controversial theories about GERD is that it may be the paradoxical result, not of too much stomach acid, but of too little. This condition, called hypochlorhydria, is known to be common in individuals over 50, especially women.

According to this theory, popularized by Jonathan Wright, MD, and others, lack of stomach acid results in poor motility, and incompletely digested food remains in the stomach, causing reflux [32]. This theory seems logical, as adequate acidification of the stomach can be a signal for gastric emptying, enabling food to transit to the small intestine.

On the other hand, the strategy can backfire: Some GERD sufferers report worsened pain when they take acid supplements like betaine hydrochloride as a digestive aid prior to meals. Therefore, a cautious empirical trial of a capsule or two of betaine HCl prior to meals (some patients prefer a tablespoon or two of apple cider vinegar) might be warranted in some cases of GERD, if it eases symptoms.

24.8 Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) was once thought to be mostly psychogenic in origin, because there were no serological markers or definitive pathological changes to set it apart from distinct organic conditions like inflammatory bowel disease (IBD). We now know that there are a variety of measurable factors that characterize it.

While essentially a diagnosis of exclusion in the absence of other disease entities deemed more "serious," IBS can roughly be categorized into diarrhea predominant (IBS-D)

or constipation predominant (IBS-C), with a considerable proportion of cases occupying the middle ground where diarrhea may alternate with constipation with associated bloating, urgency, tenesmus, mucus in the stool, and colicky pain (mixed type or IBS-M).

Recently, considerable interest has been generated about a subtype of IBS, dubbed postinfectious, which may be the long-term sequel to a bout of gastroenteritis. Symptoms persist, despite resolution of the initial infection, with no discernible traces of the implicated pathogen. The theory is that the infection may set the stage for prolonged dysbiosis; alternatively, there may be low-grade microscopic colitis, with lymphocyte aggregations seen on biopsy, but without the characteristic ulcerations or granulations pathognomonic of IBD. Indeed, a new blood test has been introduced to identify postinfectious IBS [33].

Much has been written about visceral hypersensitivity, genetically determined or acquired, in which feedback from the enteric plexus is amplified by aberrant brain circuits. From a conventional medicine standpoint, this argues for the use of bowel antispasmodics or antidepressant/anxiolytic medications. On the other hand, adopting a holistic perspective, natural modalities such as yoga, relaxation and meditation, biofeedback, hypnotherapy, and acupuncture might be invoked.

Fiber is often tapped by gastroenterologists as a panacea for IBS, but it is uncertain whether refined forms of soluble or insoluble fiber confer the benefits of plant polyphenols, present in fresh fruits and vegetables and even coffee, chocolate, spices, and tea, which may be vital substrates for cultivation of a healthy intestinal flora. For many Westerners on diets bereft of fiber, adding dietary or supplemental fiber may go a long way toward resolving digestive issues. On the other hand, overzealous fiber replacement may exacerbate IBS symptoms.

Of late, the concept of SIBO (small intestinal bacterial overgrowth) has been popularized as way of addressing IBS-D. One reason for the embrace and commercialization of this paradigm has been the introduction of the luminally active antibiotic rifaximin, which can curtail bacterial proliferation in the small intestine. But results can be temporary and equivocal, especially if patients do not address dietary precipitants of IBS.

Of course, celiac disease must be ruled out, but even in the absence of serological markers or biopsy-proven anatomical changes to the villi, non-celiac gluten sensitivity can be a major contributor to IBS [34]. While gluten elimination is mostly helpful for IBS-D, the presence of opiate-like gliadorphins in gluten may sometimes account for stubborn cases of constipation. Similarly, casomorphins from dairy products can trigger mu receptors in the colon, slowing intestinal transit.

Another way of defining optimal diets for IBS sufferers is by means of allergy testing. Conventional skin testing and IgE RAST testing are not useful for identifying food precipitants of IBS, but one study has demonstrated utility of IgG food allergy testing [35].

A useful accoutrement to antimicrobial treatment of SIBO, as well as a worthwhile starting point to test the efficacy of an elimination diet for IBS symptoms even prior to initiation of antimicrobial therapy, is the low-FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diet. Rather than a diet per se, it proposes a trial elimination of potentially problematic carbohydrates and sugar alcohols (see Table 24.2) [36, 37]. These are thought to provoke symptoms due to partial indigestibility (e.g., disaccharide intolerance), osmotic laxative action (e.g., polyols), or as a substrate for gas-generating fermentation. A recent study confirmed that IBS-D patients assigned to a low-FODMAP diet for 4 weeks obtained statistically significant symptom relief [38].

The low-FODMAP diet is not meant to be a lifelong prescription that requires rigid adherence; rather, it is a means for patients and nutritionists to identify potential food pre-

Table 24.2 Common foods high in FODMAPs

Fructose	Lactose	Fructans	Mannitol	Sorbitol	Galactans
Fruit: Apples, mango, pear, watermelon *Vegetables*: Asparagus, artichokes, sugar snap peas *Others*: Agave, high-fructose corn syrup, honey	Dairy (cow, goat, sheep)	*Fruit*: Custard apples, white peaches, nectarines, persimmon, watermelon *Vegetables*: Artichokes, garlic, leek, onion, spring onion (white part only), shallot *Grains/cereals*: Barley, rye, wheat-based food products *Nuts and legumes*: Cashews, pistachios, chickpeas, legumes, lentils *Others*: Fructo-oligosaccharides, inulin	*Fruit*: Stone fruits, peach, watermelon *Veggies*: Cauliflower, mushrooms, snow peas *Others*: Mannitol	*Fruit*: Apples and stone fruits; sugar-free candies and gum *Others*: Sorbitol	*Legumes*: Chickpeas, lentils, legumes (e.g., kidney beans, soy beans)

Based on data from Refs. [36, 37]

cipitants. Foods originally proscribed on the low-FODMAP diet that are well tolerated may be reintegrated.

Natural antimicrobials have applicability to SIBO because of their broad spectrum of action that discourages antibiotic and fungal resistance, their tolerability, relative affordability, and potential for long-term administration. These include berberine from Oregon grape root; aromatic oils from oregano, thyme, sage, and rosemary; olive leaf polyphenols; gentian; and allicin-rich garlic extracts.

Enteric-coated peppermint oil is well studied for relieving the symptoms of "spastic colon," a term formerly used for a common manifestation of IBS. In time-release form, the peppermint is released past the gastroesophageal junction, where it might exert a relaxing effect, prompting reflux. Instead, the peppermint acts on the intestinal smooth muscle, where it slows peristalsis by delaying the action potential of muscle fibers. In addition, peppermint has broad-spectrum antimicrobial effects, helping to alleviate SIBO.

Certain botanical agents possess pro-motility effects, which can overcome constipation, but also relieve the stasis which perpetuates colonization of the small intestine via translocation of inappropriate colonic bacteria. These include the carminative oils which are said to soothe the gastrointestinal tract, stimulate appetite and the release of digestive enzymes, and promote peristalsis and gastric emptying. They include fennel, cardamom, cumin, caraway, lemon balm, as well as many other herbs that are said to possess carminative properties.

Chamomile has a long tradition of use in treatment of gastroenteritis and especially IBS-D. It is thought to impart soothing and antispasmodic effects, with a mild CNS sedative component [39].

A formula consisting of nine herbs (including some of the aforementioned), STW 5 (Iberogast®), has been approved and used safely for five decades in European countries for the treatment of functional dyspepsia and IBS [40]. For constipation, a gradual ramp-up of magnesium citrate can prove helpful without the dependency of herbal laxatives that contain anthraquinones. Prebiotics from kiwi fruit, acacia, and fructo-oligosaccharides (FOS) may help to alleviate constipation, but care must be taken lest they produce uncomfortable gas and bloating (they are specifically contraindicated on the low-FODMAP diet).

Hydrochloric acid and digestive enzymes may play a role in relieving IBS symptoms by facilitating complete breakdown of food constituents.

Administration of certain strains of probiotics is documented to alleviate IBS-C [41]. Less consistent results have been seen in IBS-D. In the latter, it may be that certain species exert competitive inhibition or possess antimicrobial properties that discourage the proliferation of harmful flora. Alternatively, probiotics may exert a direct or indirect ameliorative effect on low-grade chronic intestinal immune activation that characterizes some forms of IBS. A recent pilot study showed alleviation of each of the cardinal symptoms of IBS (abdominal pain/discomfort, distention/bloating, and difficult defecation) with *Bifidobacterium* infantis; other studies have supported benefits of lactobacilli as well as the probiotic "cocktail" VSL#3® [42].

For acute diarrhea, the use of the soluble fiber pectin, along with adsorbent clays like kaolin, may rid the intestine of irritating bacterial endotoxins.

New discoveries have led us to appreciate the role that histamine may play in provoking intestinal symptoms. The intestinal lining is richly populated with mast cells that release histamine in combination with zonulin, a substance that disrupts gap junctions of intestinal epithelial cells and alters permeability. This may account for extraintestinal manifestations of not just celiac disease but also other less classic forms of food intolerance or dysbiosis.

Just as it does in the nasal passages, histamine produces hyperemia, swelling, mucous secretion, and pain in the GI tract. Histamine-mediated intestinal symptoms may be attenuated by a low-histamine diet and by administration of diamine oxidase (DAO), now available as an OTC supplement. DAO, normally produced by the intestinal epithelial cells, acts to metabolize excess histamine. The bioflavonoid quercetin also can attenuate the histamine response.

Since microscopic colitis is implicated in certain subtypes of IBS, it has been proposed that IBS sometimes represents a *forme fruste* of IBD; therefore some of the following strategies employed for IBD may be equally warranted for stubborn IBS symptoms.

24.9 GI-IBD

The term "colitis" comprises several types of inflammatory intestinal disorders, as distinguished from irritable bowel syndrome (IBS), a "functional" disorder of motility in which gross pathological changes are not apparent. The main types of colitis are ulcerative colitis (UC) (and its subtype ulcerative proctitis) and Crohn's disease (CD), which have different characteristic appearances and radiological and blood testing presentations. They are collectively referred to as inflammatory bowel disease (IBD).

There is now evidence that, on closer examination, a fairly high percentage of IBS patients actually have "microscopic colitis" in which intestinal surface cells show signs of damage, helping us to appreciate that the colitis spectrum may be wider than previously thought.

In addition, while CD and UC have not generally been thought of as infectious diseases, one form of colitis, pseudomembranous colitis, is known to be caused by a bacterium, *C. difficile*.

More researchers are coming to accept that imbalances in intestinal flora may be at the root of IBD [43]. Immune cells in the walls of the intestinal tract are engaged in continual "cross-talk" with the trillions of bacteria that inhabit our gut. When beneficial bacteria are suppressed and harmful bacteria proliferate, the intestinal defense system may go into "overdrive," resulting in an exaggerated immune response and triggering autoimmunity and consequent inflammation.

This disordered state of intestinal microbes is sometimes referred to as "dysbiosis." Evidence that dysbiosis might be a contributing factor in IBD comes from several sources. Frequent administration of antibiotics is known to be a risk factor for IBD, and UC and CD patients sometimes suffer exacerbations of their disease after antibiotics are prescribed for other conditions.

Also, use of powerful acid-blocking medications increases the risk for IBD, probably because it alters the intestinal flora. Breastfeeding, perhaps because of its "priming" effects on the intestinal immune system, appears to be protective against IBD [43].

In some studies, probiotics appear to ameliorate the symptoms of IBD [44], but no one is yet sure which probiotics work best, or in what form or dosage. Promising research [45] suggests that fecal flora harvested from healthy donors can help sufferers of IBD, but human trials are carefully regulated by the FDA and results have been mixed, with case reports of adverse consequences such as inadvertent transmission of cytomegalovirus resulting in acute exacerbation [46].

Commonly used medications sometimes play a role. Nonsteroidal anti-inflammatory drugs (NSAIDs) may set the stage for IBD by damaging the intestinal surface.

Additionally, stress provokes IBD. Anxiety and depression are associated with increased CD activity, and signals from the brain have been shown to influence inflammation by altering intestinal barrier function and even leading to changes in the composition of intestinal flora.

Whether because of overdependence on pharmacological drugs, refined foods, or other factors, IBD incidence is on the rise in developed countries, affecting as many as 1.4 million Americans, nearly 0.5% of the population. Some point to the "hygiene hypothesis," which proposes that our conquest over unsanitary conditions has increased the likelihood that our idle immune systems will inappropriately target our own tissues in a misguided attack. Supporting this notion is research suggesting that introduction of the nonpathogenic helminth *Plasmodium ovale* into the GI tracts of IBD sufferers can induce remission via immunological "decoying" [47].

The role of diet cannot be underestimated. Major changes in the Western diet have accompanied unprecedented rises in the incidence of IBD over the last 75 years. Introduction of refined and sugar- and chemical-laden foods has probably fueled the epidemic. Globalization of the food supply has rapidly introduced dairy products, cereal grains, potatoes, tomatoes, legumes, and other novel dietary items into the diets of populations not accustomed to these foods. Ubiquitous trans fats and refined omega-6 vegetable oils are thought to promote inflammation.

Certain food additives have been implicated in the causation and perpetuation of IBD. "Microparticles," such as titanium dioxide, are frequently added to food and have razor-like effects on the intestinal lining. Carrageenan, a "natural" seaweed derivative frequently added to foods to improve texture and "mouth feel," has been shown to inflame the intestinal lining in susceptible persons. Emulsifiers have recently been implicated.

This has led some to propose a return to a "paleo diet" to ameliorate the symptoms of IBD [48]. This ancestral diet highlights organic or grass-fed meat, chicken, and eggs; fish and shellfish; fresh, organic fruits and vegetables; and nuts and seeds. Conspicuously absent are grains, dairy products, legumes, nightshade family vegetables, processed and refined foods, and sugar.

Alternatively, some advocate the specific carbohydrate diet (SCD) for IBD. This grain-free, animal protein, and fruit/vegetable diet has many similarities to the paleo diet, except that it more stringently emphasizes starch avoidance while permitting fermented dairy products for those not specifically intolerant to cow's milk [49] (see ▶ Boxes 24.2 and 24.3). The goal of the SCD is to "break the vicious cycle" of microbial proliferation by denying pathogenic bacteria their preferred substrate of partially indigestible carbohydrate—much the same as the rationale for the low-FODMAP diet, with which the SCD shares similarities.

Box 24.2 Specific carbohydrate DIET (SCD)

- No disaccharides: lactose, sucrose, high-fructose corn syrup
- No grains
- No agar, carrageenan, or seaweed derivatives
- No starchy legumes (some permitted)
- No starchy vegetables (potatoes, sweet potatoes, parsnips, corn, etc.)
- No processed meats
- Based on data from Ref. [49]

Box 24.3 Foods allowed on SCD

- Unprocessed meats, eggs, poultry, fish
- Most non-starchy vegetables
- Most fruits and juices
- Plain yogurt and lactose-free natural cheese
- Nuts and nut flours for baked goods
- Pulses, navy, string, lima beans
- Oils, light tea and coffee, distilled alcohols, honey
- Based on data from ▶ www.scdiet.org

A recent first-of-its-kind study validated the benefits of the SCD in children with ulcerative colitis and Crohn's disease. At the end of 12 weeks of strict adherence to the SCD, 8 of 10 patients who finished the study showed significant improvements and achieved remission from the dietary treatment alone [50]. On the other hand, stringent limitation of oligosaccharides may, at least in theory, have adverse consequences for IBD sufferers. The selfsame banned fermentable starches, upon bacterial degradation, yield beneficial short-chain fatty acids (SCFAs) like butyrate, which nourish colonic mucosa [51]. Indeed, some human trials have shown benefits of rectal instillation of sodium butyrate for proctitis and topical application for pouchitis.

Administration of oral butyrate supplements seems to be less efficacious than encouraging endogenous production via diet. Prebiotics that promote SCFAs include resistant starches

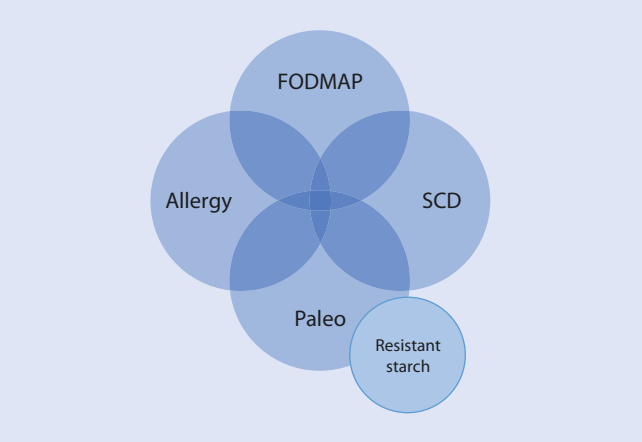


Fig. 24.3 GI diet similarities

like cooked, then re-cooled potatoes and unmodified potato starch powder (see Fig. 24.3).

There is no question that nutritional deficiencies play a prominent role in IBD. Malabsorption, diarrhea, and GI blood loss are common features of IBD, and therefore deficiencies of B vitamins, fat-soluble vitamins, and essential fatty acids—and key minerals such as magnesium, zinc, and selenium—are extremely common.

But supplementation is not just a matter of repletion of missing nutrients in IBD; certain vitamins and minerals have therapeutic effects beyond just staving off deficiency. One such nutrient is fish oil, which some studies indicate may suppress intestinal inflammation [52]. High doses are required, up to 9 g per day, delivered via enteric-coated capsules that open downstream to deliver omega-3 fatty acids directly to the intestinal epithelium.

Another is vitamin D, which studies suggest might be therapeutic at doses higher than required to simply ward off deficiency [53]. One clue comes from the finding that IBD is less commonly found at equatorial latitudes, where plentiful sun exposure seems to confer protection via production of vitamin D in the skin by UV rays. While a dose of 400 international units has traditionally been used to supplement vitamin D, doses in the thousands seem to be required to rein in inflammation and autoimmunity.

Iron is frequently low in patients with IBD because of malabsorption and gastrointestinal blood loss. Gastroenterologists, therefore, frequently prescribe potent iron supplements to their patients. But concern has arisen over the potentially pro-inflammatory and constipating effects of common iron supplements like ferrous sulfate [54]. Where possible, iron repletion via iron-rich foods like red meat and organ meats is preferable; if refractory to replacement with diet, parenteral iron may be indicated.

Natural products that have documented efficacy in IBD included curcumin [55], Boswellin [56], conjugated linolenic acid (CLA) [57], phosphatidylcholine [58], fish peptides derived from hydrolyzed white fish [59], aloe vera gel [60], EGCG from green tea [61], N-acetyl glucosamine [62], melatonin [63], and enteric-coated propionyl-L-carnitine [64] (see Table 24.3).

Table 24.3 Nutraceuticals for IBD

Curcumin	EGCG (green tea polyphenol)
Boswellin	N-acetyl glucosamine (NAG)
Conjugated linolenic acid (CLA)	Melatonin
Phosphatidylcholine	Propionyl-L-carnitine (GPLC)
Fish peptides	Omega-3
Aloe	

A traditional naturopathic remedy for bowel disorders is Bastyr (Robert's) Formula B, consisting of marshmallow, wild indigo, geranium, goldenseal, slippery elm, ginger, okra powder, niacinamide, and duodenum powder.

Probiotics may play a role in ameliorating IBD. Long-standing European experience with *Escherichia coli* Nissle 1917 (Mutaflor®) suggests benefits, but the formulation is not approved for importation to the United States. VSL#3®, a high-potency probiotic mixture, has been the object of several trials, including some that were double-blind placebo-controlled, with significant impact on improved stool frequency, self-reports of pain, physician assessment, and endoscopic scores [65].

Comfrey, a once-preferred gastrointestinal healing herb, has now fallen into disfavor because of its high content of hepatotoxic pyrrolidine alkaloids.

While there is evidence that administration of a wide variety of oral supplements and nutraceuticals may be justified in IBD, caution must be exercised. Many patients suffer from chronic diarrhea, cramping, and abdominal pain, or may have narrowing of segments of the intestine. A gradual introduction may be warranted, with supplements added only as tolerated.

As documented above, GI disorders are exceptionally amenable to natural interventions. These functional medicine strategies possess several advantages: (1) Preferential use of diet modification and nutraceuticals in lieu of pharmaceuticals generally minimizes serious side effects. (2) By comprehensively addressing the *causes* of GI complaints, natural approaches provide more than just transient, symptomatic relief. (3) Because of the centrality of the microbiome to overall health, and its role in the pathogenesis of what were previously thought to be "remote" diseases, functional medicine strategies contribute to long-term overall health optimization.

It is high time that such approaches take their rightful place in modern medicine's armamentarium. The pace of ongoing research guarantees that there will be an ever-expanding evidence base rationalizing their deployment.

25.1 Introduction

Strange but true, our bodies have more bacteria than we have human cells. The microbiome is inhabited by 100 trillion microorganisms, about 10 times the number of cells in the human body. Of note, it weighs 2–6 pounds. A dysfunction in this system significantly affects mental, emotional, and physical health [1]. It is estimated that the microbiome contributes 150–360 times more bacterial genes than human genes [2, 3].

The word microbiome is defined as the collection of microbes or microorganisms that inhabit an environment. It includes communities of symbiotic, commensal, and pathogenic bacteria, fungi, and viruses. The clusters of bacteria from different regions of the body are known as microbiota: skin microbiota, oral microbiota, vaginal microbiota, and GI microbiota. Scientists have recently come to understand that our GI microbiota, as a whole, determines whether pathogens in the gut coexist peacefully or cause disease [4].

Bacteria are distributed throughout the intestine, with the major concentration of microbes and metabolic activity found in the large intestine: It is commonly known as the intestinal microbiome. The intestinal microbiota are made up of 1000 species comprised of up to 130 trillion microbes, 70% of which cannot be cultivated in a microbiology laboratory [5, 6].

The gut microbiome is essential for the host for digestion, including the breakdown of dietary fibers and complex carbohydrates, the synthesis of vitamins, and the production of short-chain fatty acids. The balance and makeup of the microbiota play a critical role in metabolic functions [7]. The intestinal microbiota is essential to nutrient metabolism, opportunistic pathogen defense immune system development, and intestinal barrier function. About 70% of our immune cells reside in the GI tract. The development of the intestinal immune system is largely dependent upon exposure to microorganisms.

Scientists are conducting research which documents the significant impact of the gut on brain health. The National Institutes of Health devote millions of research dollars to understand these complex interactions. More than 90% of over 4000 articles on the microbiome were published in PubMed in the past 5 years [8]. While some physicians and scientists see probiotics as the "new magic medicine," it is far from new. Élie Metchnikoff received the Nobel Prize in Physiology or Medicine in 1908 for his work in discovering probiotics and phagocytes.

In the exciting area of research, one of the open questions is how chronic inflammation might be initiated and maintained in illnesses such as depression, and what the gut has to do with this. Emerging studies show that the normally very selective intestinal barrier may be compromised in depression (and in numerous conditions where depression is often a hallmark symptom) [9–11].

Psychological stress and exhaustive exercise have been shown to increase the permeability of the intestinal barrier [12–14]. However, a Westernized diet high in fat and sugar has also been shown to cause a more porous intestinal lining, the consequences of which include systemic access to food antigens, environmental toxins, and structural components of microbes, such as lipopolysaccharide endotoxin (LPS) [15]. The latter agent, LPS, is particularly important regarding depression; even relatively small elevations in systemic LPS levels have been shown to provoke depressive symptoms and disturb blood glucose control [16–22]. Endotoxins such as LPS can decrease the availability of tryptophan and zinc, thereby negatively influencing neurotransmission [23, 24]. Moreover, systemic LPS can elevate inflammation and oxidative stress. Traditional dietary practices have completely divergent effects of blood LPS levels; significant reductions (38%) have been noted after a one-month adherence to a prudent (traditional) diet, while the Western diet provokes LPS elevations [25]. These and other findings help establish mechanisms whereby the LPS-lowering, antioxidant, and anti-inflammatory properties of broad traditional dietary practices, as well as specific components within them, can help provide mood support. Indeed, when the limitation of intestinal absorption is overcome, individual phenolic structures have been shown, at least experimentally, to curb the breakdown of central neurotransmitters, mimicking the proposed mechanistic properties of some primary antidepressant medications [26, 27].

25.2 Dysbiosis

The term "dysbiosis" refers to situations where microbial composition and functions are shifted from their normal beneficial state to another that may be harmful to one's health. The microbiota dysbiosis may negatively impact CNS functioning through various pathways known as the brain-gut axis [28–30]. The brain-gut axis is impacted by intestinal permeability. Another name used for intestinal permeability is leaky gut (see ▶ Box 25.1).

Box 25.1 Intestinal Permeability (Leaky Gut)
- Modulation of local and systemic inflammation
- Decreased digestion and absorption of nutrients
- Decreased brain-derived neurotrophic factor (BDNF)
- Increased small intestinal bacterial overgrowth (SIBO)

Dysbiosis of the gut microbiota has profound effects on immune function and leads to inflammation. One common cause of dysbiosis is the Western diet as it affects both immune homeostasis and the gastrointestinal tract. For example, a high-sugar-content diet allows for the overgrowth of *Clostridium difficile* and *Clostridium perfringens* by increasing bile secretion. This dysbiosis can lead to metabolic syndrome, diabetes, obesity, celiac disease, inflammatory bowel disease, and irritable bowel syndrome.

One of the most important roles of the microbiota is the development and sustainment of local and systemic immunity through homeostasis of its environment. This has been demonstrated in studies showing the expansion of T and B cells in mesenteric lymph nodes and Peyer's patches, including $CD4^+$ cells and FOXP3 T_{reg} cells [31, 32]. An altered gut microflora has been reported in patients with rheumatoid arthritis and other autoimmune diseases as well as in allergic disease, implying that the normal gut microflora constitutes an ecosystem responding to inflammation in the gut and elsewhere in the human body.

25.3 Probiotics

Gut microbiota may be modulated with the use of probiotics, antibiotics, and fecal microbiota transplants as a prospect for therapy in microbiota-associated diseases. Probiotics can stabilize the gut microbiota and the intestinal permeability barrier, and they can improve the degradation of enteric antigens and alter their immunogenicity by countering the progression of inflammation.

In addition, probiotics can improve the immunological barrier, in particular the intestinal immunoglobulin A response. They are also able to mediate the balance between pro- and anti-inflammatory cytokines, thereby quelling the inflammation [33–36]. Probiotics can decrease inflammation.

Probiotics are on a dramatic growth curve. Probiotics are live microbial food supplements or components of bacteria, which have been shown to have beneficial effects on human health. It is estimated that the global probiotics market will exceed $46 billion by 2022 [37]. We are undoubtedly in an exciting period for probiotics. Probiotic products are entering the marketplace in all shapes and forms including yogurt, juices, and even chocolate. Probiotics are being adapted to almost everything that is ingestible. This raises the question as to whether or not these new food sources are just trendy or if they can effectively provide benefit. In terms of labeling probiotic products, the only standard required by the FDA for foods, supplements, and medical foods is that the labeling be truthful and not misleading. Sometimes, there is a disconnect between what's studied in published papers and what is actually available commercially on the market, but there are some well-validated, properly labeled products out there and those are the ones that should be utilized [38].

A probiotic should be able to survive the gastric barrier and bile acids to make it through the gastrointestinal tract (GIT) and reach the colon. It should have the ability to colonize the intestinal tract to perform its functions as a probiotic. A probiotic should be able to improve mucosal immunity and support barrier function. It should be able to competitively exclude pathogenic microbes. *Bacillus subtilis* are spore-forming bacteria and is one of the species of the *Bacillus* genus that fit these criteria; these spores survive the transit through the stomach and small intestines to reach the microbiome in the colon where they germinate, proliferate, and then resporulate [39–45].

Studies have shown that orally ingested *B. subtilis* spores are immunogenic and can disseminate to the Peyer's patches and mesenteric lymph nodes [46–52]. In this way, they offer some advantages over the more common *Lactobacillus*. The average over-the-counter probiotic typically has Lactobacilli and Bifidobacter organisms in various amounts, with some trying to outdo the other with larger and larger amounts of organisms. The gastric survival of these has been shown to be low as many are not acid-stable. The probiotic paradox is that dead cells can generate responses from the GIT, mainly immunomodulatory rather than antimicrobial [53].

The GI tract, with changes in pH, bile salts, and digestive enzymes, may require large numbers of probiotics to be consumed so that adequate numbers reach the lower GI tract. Most probiotics today emphasize the number of live bacteria. Lahtinen [54] suggests a product of fermentation may not require the probiotic to be viable when consumed and the probiotic will still be beneficial.

There is no consensus to the minimum number of bacteria needed to produce a beneficial effect on health. Studies such as McNulty and colleagues have shown that probiotics need to be consumed every day because they do not colonize the gut [44].

Probiotics reinforce the various lines of gut defense: immune exclusion, immune elimination, and immune regulation. Probiotics also stimulate nonspecific host resistance to microbial pathogens and thereby aid in their eradication. There is evidence for the use of probiotics for reducing anxiety in individuals with altered GI function, in addition to lowering systemic inflammatory cytokines and decreasing oxidative stress [55]. Messaoudi et al. found *Lactobacillus helveticus* combined with *Bifidobacterium longum* decreased anxiety in humans accompanied with a reduction in urinary free cortisol in treated humans [56]. *Lactobacillus rhamnosus* has been found to decrease anxiety and alters expression of GABA receptors in the brain, a receptor known to play a role in anxiety disorders [57]. Probiotics have also been promising as a potential preventative strategy for depression in human trials [58]. Moreover, there is evidence that the concentration of fatty acids, namely, arachidonic acid and docosahexaenoic acid, is increased in mice that received a strain of *Bifidobacterium breve* [59]. It is known that both fatty acids contribute to several neurodevelopmental processes, including neurogenesis and neurotransmission, and can impact such cognitive functions as learning and memory [60].

There is quite an amount of research evidence supporting the effectiveness of probiotics; however, the mechanisms of action are less clear. They may competitively exclude gut pathogens by repairing leaky gut or producing antimicrobial properties. Additionally, they may stimulate the immune system by increasing the production of anti-inflammatory cytokines [61]. They also communicate with the CNS via the vagus nerve and impact brain function.

Probiotics protect the inflamed intestinal epithelium. Competition for binding sites and inhibition of pathogen growth stimulate the immune system, including the stimulation of anti-inflammatory cytokines and enhancement of barrier function [62].

Regardless, multiple studies confirm the presence of a microbiota-gut-brain axis, and thus it is clear that probiotics can modulate aspects of brain function and brain health. Further research is needed to identify additional organisms and elucidate the underlying mechanism of actions.

While the focus of this chapter is intestinal microbiome, many different health targets have been studied with probiotics. One probiotic should not be expected to do all of these things, however. In general, the best evidence for probiotic health effects is in the area of decreasing duration or incidence of certain diarrheal diseases and in immune enhancement. Emerging evidence exists for probiotics in the areas of dental caries; prevention of allergy, intestinal infections, vaginal infections, and colds and respiratory infections; improved growth parameters in undernourished children; and improvements in quality-of-life indicators [63].

25.4 Second Brain

People may refer to the enteric nervous system (ENS) as an intuitive feeling, describing its actions as a "gut response" or "gut decision." So it is no surprise to find that the GI tract releases neurotransmitters that affect brain health and decision-making. The ENS is embedded in the wall of the digestive tract and is localized by the myenteric plexus and submucosal plexus. This system contributes to GI motility, nutrient handling, gastric acid secretion, and immune function.

As researchers gain a deeper understanding of ENS, this second brain located in the GI tract, it is clear that it is filled with neurotransmitters [64]. Together, the gut-brain connection significantly determines mental states and plays key roles in certain diseases throughout the body. While the second brain has an important role in brain health, it does not appear to participate in conscious thoughts or decision-making. "The second brain does not help with the great thought processes…religion, philosophy, and poetry is left to the brain in the head," says Michael Gershon, chairman of the Department of Anatomy and Cell Biology at New York–Presbyterian Hospital/Columbia University Medical Center, an expert in the field of neurogastroenterology, and the author of the Second Brain [64].

A dysfunction in the gut-brain axis is linked to neuropsychological, metabolic disorders such as obesity, immune, and endocrine disorders [65]. Dysbiosis has been linked to depression and autism spectrum disorder (ASD) and GI disorders including IBD and IBS [66] (see ▶ Box 25.2).

Box 25.2 Gut ⟹ Brain

- Influences from the gut affecting the brain
- Dysbiosis
- Antibiotics and infections
- Environmental influences:
- Toxins
- Food and gluten sensitivities
- Genetic predisposition
- Nutrition and physical activity
- GI neurotransmitters
- Inflammatory cytokines
- Mode of delivery at birth

It is clear that the gut microbiota can be a key regulator of mood, cognition, pain, and obesity [67]. The microbiota-gut-brain (MGB) axis and the neuroimmune system provide understanding and management of anxiety, ADHD, autism, cytokines, depression, stress, and neuroimmune conditions [68]. Major depression and anxiety states are common in patients presenting with IBS.

Immune cells produce neurotransmitters. There are several mechanisms that facilitate neuroimmune interactions and the bidirectional communication. These include the anatomical proximity between immune cells and nerve cells, the receptors for neurotransmitters on immune cells, and for immune mediators on nerves and the intracellular signaling pathways that modulate nerve and immune phenotype expression and function [69]. Chronic active inflammation in the GI tract leads to neuroimmune plasticity, resulting in remodeling of both the neural and immune systems.

Gut microbiota and some probiotics can regulate immune functions. Benefits may be anti-inflammatory actions of certain bacteria and a capacity to affect HPA axis activity. Most physical and mental diseases have inflammation as their root cause. Much of our immune system, about 70%, is located in the gut microbiome [68].

When food enters the mouth and passes through the digestive system, it sends the brain a multitude of interacting signals that are filled with sensory, nutritive, and other information. According to Cenit [70], gluten sensitivity is a result of dysbiosis, not a genetic disorder. This may explain, in part, why patients who test positive for the celiac gene may not be gluten-sensitive while those patients who test negative for the celiac gene may have a gluten sensitivity. Dysbiosis is most prominent in the digestive tract or on the skin, but it can also occur on any exposed surface or mucous membrane. Dysbiosis creates inflammatory factors responsible for developing insulin resistance and body weight gain [70] (see ◘ Fig. 25.1). These conditions, in turn, create inflammation which can affect brain function and brain health.

Most information received by the brain relating to GI contents and activity is generally transmitted via vagal afferent feedback. The other enteric nervous system source is the

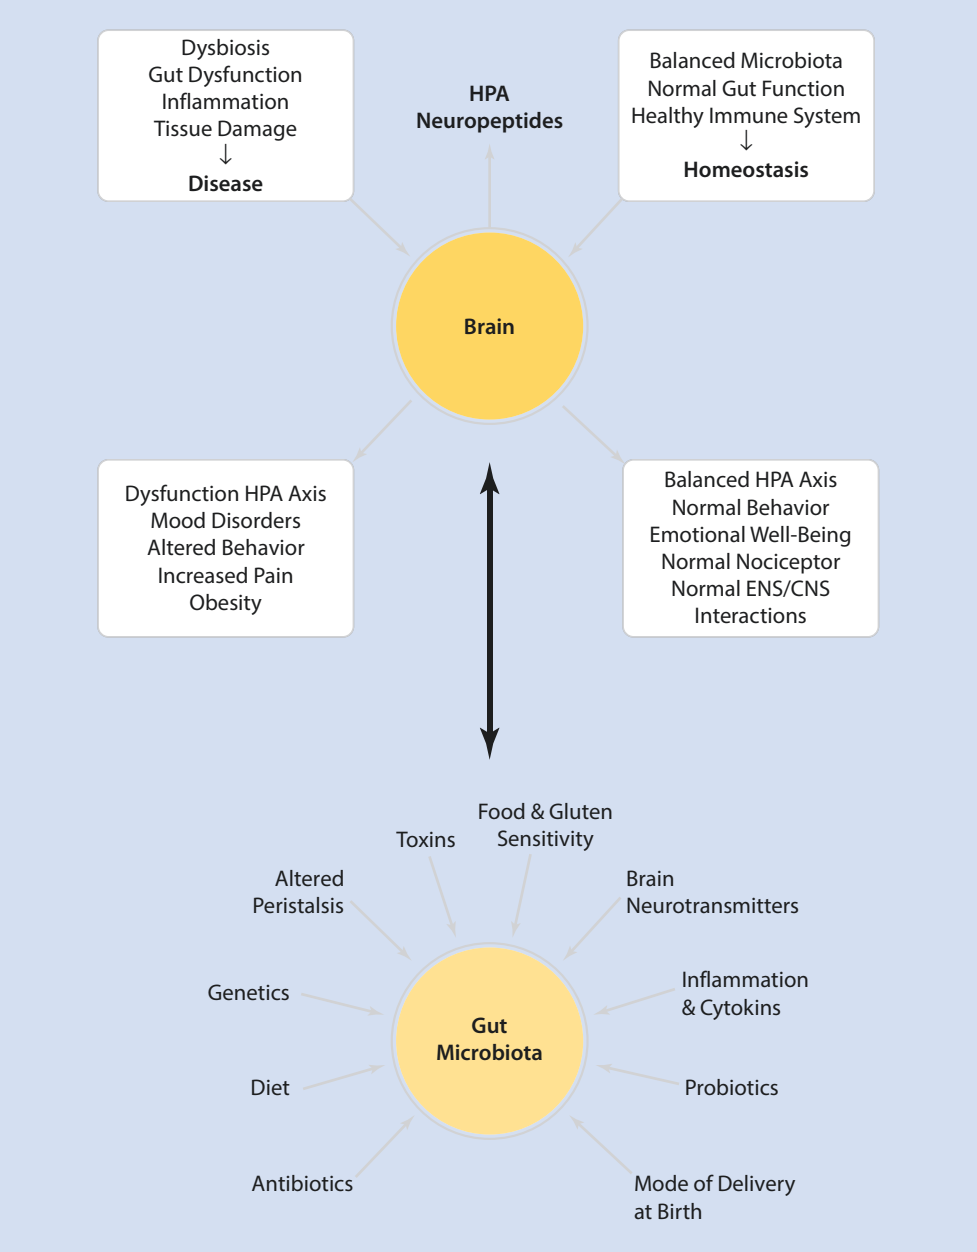

Fig. 25.1 Gut–brain interactions

spinal cord afferents, which mediate GI pain rather than providing feedback to the brain relating to nutrient contents.

25.5 Mood Disorders

Conversely, visceral pain can affect central pain perception, mood, and behavior. Communication between the central nervous system (CNS) and ENS involves neural pathways as well as immune and endocrine mechanisms [71] (see ► Box 25.3).

Box 25.3 Brain ⟹ Gut

- Influences from the brain affecting the gut microbiota [72]
- The hypothalamus-pituitary-adrenal (HPA) axis
- The CNS regulating areas of satiety
- Neuropeptides released from sensory nerve fibers

Chronic psychological stress is associated with a greater risk of depression, cardiovascular disease, diabetes, autoimmune diseases, upper respiratory infections, and poorer wound

healing [73]. Stress induces leaky gut and increases mucosal immune response, which in turn alters the composition of the microbiome and leads to enhanced HPA drive. The hypothalamus is an integral part of the limbic system referred to as the "emotional" brain. The limbic system anatomically consists of the hypothalamus, amygdala, medial thalamus, and anterior cingulate cortex (ACC). Psychosocial factors can influence digestive function, symptom perception, illness behavior, and outcome [74].

Lackner and colleagues [75] reported a series of six individuals with irritable bowel syndrome (IBS) and six controls. Patients with IBS were treated with a 10-week course of cognitive therapy. Treatment was associated with a significant reduction in anxiety and digestive symptoms. PET scans showed reduced activity in the region of the left amygdala and right ACC following therapy [75].

25.6 Schizophrenia

The development of schizophrenia can be linked through the role of microbiota in regulating brain development, immune function, and metabolism. The evidence suggests possible microbiota alterations in schizophrenia resulting in structural damage to the GI tract, and a heightened immune response to infections, food antigens, and gluten sensitivity (see ▶ Box 25.4). Evidence that patients with schizophrenia may have altered microbiota [76]:

Box 25.4 Altered Microbiota in Psychiatric Disorders

- Structural damage to the GI tract in schizophrenia
- Abnormal response to infections pathogens in schizophrenia
- Abnormal response to food antigens in schizophrenia
- Sensitivity to gluten and bovine casein

A recent study on the oral microbiome and schizophrenia has shown large differences between case and control individuals in terms of bacterial, viral, and fungal composition [77]. Schizophrenics had increased levels of lactic acid bacteria. Individuals with schizophrenia had decreased levels of many nonpathogenic bacteria and increased levels of intestinal immune activation as indicated by antibodies to food and intestinal antigens. The microbiome was significantly altered by probiotic therapy with a tendency toward normalization in the case individuals following treatment.

Major depressive disorders, bipolar disorder, and schizophrenia have been associated with immune responses, supporting the concept that mood disorders are related to inflammatory cytokines (see ▶ Box 25.5). The findings from clinical studies demonstrate an upregulated immune and inflammatory status in patients with schizophrenia [78] and a correlation between the level of inflammatory markers and severity of clinical symptoms [79]. It has been suggested that the uncontrolled neuroinflammation by pro-inflammatory cytokines is involved in the pathogenesis of schizophrenia [74]. Chronic macrophage activation and secretion of interleukin-2 and interleukin-2 receptors have been proposed as the basic biological mechanism of schizophrenia in earlier papers [74]. For example, the protozoa *Toxoplasma gondii* is known to cause major perturbation to the gut microbiota and is a recognized environmental risk factor for schizophrenia [74]. More recently, a chlorovirus (family *Phycodnaviridae*) has been identified in humans that affects cognitive function relevant to schizophrenia in animal models [74].

Box 25.5

Inflammation ⇒ Cytokines ⇒ HPA ⇒ Mood disorders

N-methyl-D-aspartate (NMDA) receptor hypofunction is believed to be central to the pathophysiology of schizophrenia, as NMDA receptor antagonists produce schizophrenia-like symptoms while agents that enhance NMDA receptor (R) function reduce negative symptoms and improve cognition [74]. Variation in brain-derived neurotrophic factor (BDNF) expression is believed to play a role in the molecular mechanism underlying cognitive dysfunction in schizophrenia [74]. Given that normal development of the microbiota is necessary to stimulate brain plasticity through the appropriate expression of BDNF and NMDA receptors, it is possible that altered microbiota may contribute to the NMDA receptor dysfunction seen in schizophrenia [74].

25.7 Bipolar Disorder

Severance and colleagues [80] recently measured serological surrogate markers of bacterial translocation (soluble CD_{14} (sCD14) and lipopolysaccharide binding protein (LBP)) in bipolar subjects and schizophrenia subjects compared to controls. In bipolar disorder, sCD_{14} levels were significantly correlated with anti-tissue transglutaminase IgG ($r^2 = 0.037$, $P < 0.001$). The authors concluded that these bacterial translocation markers produced discordant patterns of activity that may reflect an imbalanced, activated innate immune state. Whereas both markers may upregulate following systemic exposure to gram-negative bacteria, autoimmunity, and non-lipopolysaccharide-based monocyte activation, and metabolic dysfunction may also contribute to the observed marker profiles [80].

25.8 General Discussion of Mood Disorders

Poor mental health has been associated with an increased likelihood of eating unhealthy foods [81]. Different diets create different gut flora. One study showed that rural African children eating a polysaccharide-rich diet had more Bacteroidetes

and diversity than European Union children eating the Western diet [82]. In a 2014 study in *Nature*, it was indicated that these changes can happen in the human gut—within three or 4 days of a big shift in what one eats! [83] A variety of population studies have linked traditional dietary patterns with lowered risk of anxiety or depression [74]. More recent prospective investigations have shown that traditional healthy dietary patterns are associated with a 25–30% lower risk of depression [84, 85].

Microbes produce neurotransmitters and the gut microbiota produces three-fourths of the neurotransmitters in the body. More than 50% of the body's dopamine and 95% of your body's serotonin are produced in your gut, along with about 30 other neurotransmitters [86, 87]. These molecules are critical for signaling between cells of the nervous system. Dopamine and serotonin in the brain and the GI have both been shown to be involved in the regulation of eating behavior [88].

A decade ago, prior to the scientific hypothesis of Logan et al., the notion that the intestinal manipulation of the gut microbiota could provide therapeutic value to relieve depression and fatigue was, at the very least, outlandish [89, 90]. The mechanisms of probiotics and fermented foods are complex and may be related to their role in making neurotransmitters, decreasing oxidative stress, or improving cellular repair [91]. How can this happen? ▶ Box 25.6 shows mechanisms proposed by Logan and others that have been subject of study [89–91].

Box 25.6 Association of Gut Microbiota and Therapeutic Value in Mood Disorders

- Direct protection of the intestinal barrier
- Influence on local and systemic antioxidant status, reduction in lipid peroxidation
- Direct, microbial-produced neurotransmitter production, for example, gamma-aminobutyric acid (GABA)
- Indirect influence on neurotransmitter or neuropeptide production
- Prevention of stress-induced alterations to overall intestinal microbiota
- Direct activation of neural pathways between gut and brain
- Limitation of inflammatory cytokine production
- Modulation of neurotrophic chemicals, including brain-derived neurotrophic factor (BDNF)
- Limitation of carbohydrate malabsorption
- Improvement of nutritional status, for example, omega-3 fatty acids, minerals, and dietary phytochemicals
- Limitation of small intestinal bacterial overgrowth
- Reduction of amine or uremic toxin burden
- Limitation of gastric or intestinal pathogens (e.g., *Helicobacter pylori*)
- Analgesic properties

Microbiota influence brain chemistry and consequently behavior. *Clostridium difficile* (CD), the hospital-based gut infection that kills 14,000 people each year in the USA, is associated with depression and dementia [92]. Two antidepressants, mirtazapine (Remeron) and fluoxetine (Prozac), are linked to a nearly 50% increased risk for CD infection [92].

Stress induces a dysbiosis, which in turn can trigger anxiety and depression [93–95]. Commensal bacteria modulate brain biochemistry and behavior through the vagus nerve , affecting neurotransmitters. Prolonged stress triggers unfavorable shifts in bacterial composition and diversity. Populations of beneficial microbes die off and dysbiosis flourishes [93–95]. More than one-third of people with depression have "leaky gut," the permeability of the gut lining that allows bacteria to enter the bloodstream (see ▶ Box 25.7).

Box 25.7 Serotonin's Role in the Gut [96]

- Motility patterns and gastric emptying
- Secretion
- Immune system
- Pain and discomfort
- Nausea and vomiting
- Alters microbiome
- Circulating 5-HT has the potential to impact many other tissues
- Promotes homeostasis
- Influences bone development
- Receptor sites on immune cells B and T lymphocytes
- Mast cells, macrophage, and T-cells synthesize 5-HT

25.9 Psychobiotics

The close relationships between gut microbiota, health, and disease have led to a great interest in using probiotics and/or prebiotics to prevent or treat disease [97]. The influence of probiotics on moods is significant. Psychobiotics is an emerging class of probiotics of relevance to psychiatry and mood disorders. A psychobiotic is a live organism that produces a health benefit in patients suffering from mood disorders. Such mind-altering probiotics act via their ability to produce various biologically active compounds [98].

Moreover, preliminary placebo-controlled human studies have shown that oral probiotic microbes can decrease anxiety, diminish perceptions of stress, and improve mental outlook [99]. Michael Messaoudi and colleagues from France evaluated *Lactobacillus helveticus* and *Bifidobacterium longum* combination probiotic, which was orally administered for 1 month in a one-month placebo-controlled study [100]. Among the otherwise healthy adults, significant improvements in depression, anger, anxiety, and lower levels of the stress hormone cortisol versus placebo were noted.

Bacteria are capable of producing and delivering GABA and serotonin, which are on the brain-gut axis [101]. Microbes that actively secrete GABA in the gut are strains of *Lactobacillus* and *Bifidobacterium*. Psychobiotics produce psychotropic effects on behavior, affecting the HPA axis and neurochemicals in the brain [98]. As cited by John F. Cryan, PhD, "two varieties of *Bifidobacteria* were more effective than escitalopram (Lexapro) at treating anxious

and depressed behavior in a lab mouse strain known for pathological anxiety" [98].

Alterations in microbiota influence stress-related behaviors. GI tract bacteria, including commensal, probiotic, and pathogenic bacteria, can activate neural pathways and CNS signaling systems [102]. The MGB axis may provide novel approaches for prevention and treatment of mental illness, including anxiety and depression [102].

Tests revealed that chronic ingestion of probiotic *Lactobacillus plantarum* significantly reduced anxiety-like and depression-like behaviors [103]. It also reduced Lambert-Eaton Myasthenic Syndrome-induced elevation of serum corticosterone.

Lactobacillus plantarum also reduced inflammatory cytokine levels and increased anti-inflammatory cytokine levels in the serum. Furthermore, the dopamine levels in the brain were significantly increased. The psychotropic properties of certain bacteria have great potential for improving stress-related symptoms [103].

Lactobacillus rhamnosus is a bacterial strain that has been shown to reduce anxiety and depression in anxious mice [104]. *L. rhamnosus* markedly increased GABA levels. A number of microbes can produce other neurotransmitters, such as norepinephrine, serotonin, and dopamine. *Bifidobacterium infantis*, taken as a probiotic, alters serotonin levels just like Prozac but without the undesirable side effects [105].

The National Institute of Mental Health labels anxiety as a learning deficit because the brain is unable to learn to discriminate between dangerous and benign situations [106]. Recent research has led scientists to believe that the protein is an essential ingredient in combating anxiety. Scientists think this is due to the fact that it helps the brain learn to essentially work around the fear and create positive memories. In addition, higher levels of the protein ramp up levels of serotonin, which calms the brain down and increases the sense of safety [106].

Numerous studies have shown capability of bacteria in producing neurotransmitters and neuromodulators, including gamma-aminobutyric acid (GABA), norepinephrine, serotonin, dopamine, and acetylcholine [107]. Further, findings from germ-free animals indicated a decreased level of brain-derived neurotrophic factor (BDNF), important neurotrophic factor in neuronal growth and survival, and a reduced expression of some subunits of N-methyl-D-aspartate (NMDA) receptors involved in most abundant neurotransmission in the brain. The glutamatergic NMDA receptors, involved in excitatory neurotransmission of brain waves, engage the neural circuits involved in learning and memory [107]. GABA is the major inhibitory neurotransmitter in the CNS. Dysfunctions in GABA signaling are linked to anxiety and depression, defects in synaptogenesis, and cognitive impairments [107]. From these considerations, it can be concluded that, at least through contributing in neurotransmitter synthesis or receptor expression, probiotics might adjust the brain activity.

Accumulating evidence from experimental studies supports the hypothesis that—via affecting inflammation, endocrine system, and neurotransmission—the gut microbiome takes a crucial role in the CNS function [107]. Accordingly, it is suggested that dysfunction of the neuroendocrine system, behavior, and cognition is correlated with gut microbiota dysbiosis [74]. These considerations led to establishing the term "psychobiotics" to highlight the potential effects of probiotics in treatment of mental disorders [107].

Consistently, in a meta-analysis study, Kasińska and Drzewoski [108] reported a reduced homeostatic model of assessment for insulin resistance (HOMA-IR) and insignificant fasting plasma glucose (FGP) in probiotic-treated subjects [107]. Mazloom and colleagues [109] also reported that probiotic supplementation had no significant effect on fasting blood glucose, markers of insulin metabolism, and lipid profiles [107]. Consumption of symbiotic bread containing the heat-resistant probiotic *Lactobacillus sporogenes* (1×10^8 CFU/g) for 8 weeks also decreased the serum triglyceride and VLDL concentrations in patients with type 2 diabetes [107]. Probiotics have been shown to modulate many chronic illnesses. Decreasing inflammation and improving chronic disease have a significant impact on brain health.

25.10 Brain-Derived Neurotrophic Factor (BDNF)

In the past, it was believed that the brain was hardwired with a finite number of neurons. If a brain was damaged or diseased, there was little that could be done to reverse the injury. However, today we know that the brain is neuroplastic and significant regeneration can occur with a wide variety of therapies. Brain-derived neurotrophic factor (BDNF) is a protein produced inside nerve cells [106]. Although neurotransmitters like dopamine and serotonin are important in helping the brain function because they carry the signals of neurons, the protein BDNF builds and maintains the brain circuits which allow the signals to function [106]. Therapies that may be used include treating the root cause, cytokine signaling, increasing BDNF, lifestyle factors, and suppressing inflammation in the body. Increasing the expression of BDNF in the brain can be done by supplementing the excitatory neurotransmitter, glutamate, and increasing physical activity [106].

BDNF improves the function of neurons, encourages their growth, and strengthens/protects them against premature cell death [106]. It also binds to receptors at the synapses to improve signal strength between neurons. Essentially, the more BDNF in the brain, the better the brain works. Exposure to stress and the stress hormone cortisone and depression have been shown to decrease the expression of BDNF. Various studies have shown possible links between BDNF and conditions such as depression [110, 111], schizophrenia [63], obses-

sive-compulsive disorder [64], Alzheimer's disease [65], Huntington's disease [66], Rett syndrome [67], and dementia [68]. Ratey pointed out that a study of 30 depressed people found they all had low levels of BDNF [106].

25.11 Neurological Disorders

Encased in bone— our skull—the brain is our most protected organ. It weighs 3 pounds (1.36 kg), or approximately 2% of our body weight, yet it uses 20% of our body's oxygen and calories. Within the brain are approximately 100 billion neurons, with approximately 1000 synaptic connections per cell. In the visual cortex, there are approximately 12,000 synapses per cell, and in the prefrontal cortex, this increases to 80,000 synapses. The transmission speed along axons is measured at 200 miles per hour (322 km/h) [116].

Coursing throughout the brain to reach each neuron are capillaries, more than 400 miles (644 km) of them. These capillaries are not your ordinary ones; these are lined with specialized endothelial cells (ECs) and tight junctions, forming the blood-brain barrier (BBB). The BBB functions to help vital brain nutrients pass into the brain, protects the brain from plasma components, preserves the homeostasis of the brain, and directs inflammatory cells in response to an intracerebral event [74].

Where there is an intracerebral hemorrhage, ischemic injury, trauma, or neurodegenerative progression, plasma components, including red blood cells and leukocytes, cross the BBB and produce neurotoxins that may lead to abnormal synaptic and neuronal functions [74]. Tight junctions help the BBB's permeability to blood-borne solutes, which is dependent on their molecular weight and lipophilic and hydrophilic characteristics.

The consequences of central nervous system (CNS) inflammation are increased permeability of the BBB and leukocyte infiltration of the brain, both found in multiple sclerosis (MS). Major factors in the progression of MS are $CD4^+$ interleukin-17 (IL-17)-producing T lymphocytes (Th_{17}) with IL-17 known to disrupt tight junctions in the ECs [66].

Further, T lymphocyte cerebral infiltration has been shown in patients with Alzheimer's disease (AD) and Parkinson's disease (PD). These again increase the permeability of the BBB [62, 99, 103–105]. Mounting evidence, both clinical and experimental, demonstrates the importance of BBB and any abnormalities of its functions, as well as their role in contributing to the progression of a number of inflammatory, infectious, and neurodegenerative diseases, especially in our aging population.

Acute stress increases GI and BBB permeability through activation of mast cells (MCs), which express high-affinity receptors for cortisol-releasing hormone (CRH). Chronic stress disrupted the intestinal barrier through MC activation and permitted penetration of luminal antigens, microflora metabolites, toxins, and lipopolysaccharide (LPS) in the systemic circulation and the CNS [39]. A molecule, called "microRNA-155," is responsible for cleaving epithelial cells to create microscopic gaps that let material through [40].

25.12 Alzheimer's Disease

The microbiota is a dynamic ecosystem which is influenced by several factors including genetics, diet, metabolism, age, geography, antibiotic treatment, and stress [46]. In addition, animal studies imply the necessity of an optimal function of what is known as the microbiome-gut-brain axis (MGB) in the behavioral as well as electrophysiological aspects of brain action [47].

There are correlations between microglial immunoreactivity and neuronal viability in Alzheimer's disease (AD) brain tissue. Immunohistochemical analysis demonstrated AD brain tissue expressed areas of diffuse fibrinogen indicative of a weakened BBB [41].

More than 40 million individuals throughout the world suffer from Alzheimer's, a disease for which there is no specific treatment. We know that Alzheimer's is an inflammatory disease. It is also known that gut bacteria can increase inflammation and probiotics can decrease inflammation.

Alzheimer's disease (AD) is recognized as one of the most common forms of senile dementia [43]. AD begins with memory loss of recent events (short-term memory impairment) and finally robs patients of their sense of self [44]. Increased biomarkers of oxidative stress [74], inflammation, and chronic neuroinflammation are reported to be associated with many neurodegenerative disorders of the central nervous system (CNS) including AD [45]. See ▶ Box 25.8 for emerging information on promotion of AD [43–45, 74].

Box 25.8 Emerging Information on Promotion of Alzheimer's Disease

Toxins
Too much sugar
Too many antibiotics and given too young = leaky gut
C-sections, no breastfeeding, no skin-to-skin contact with parents
Too many medications = leaky gut
Low-fat diets
Amalgam fillings
Genetically modified organisms/GMO = leaky gut
Poor methylation = epigenetics

There is a preliminary research on the effect of probiotics on the prognosis of cognition [48]. However, data on the effects of probiotics on improving cognitive disorders are scarce

[49]. Gareau reported that intestinal dysbiosis in germ-free animals (containing no microbiota), bacterial infection with an enteric pathogen, and administration of probiotics can modulate cognitive behaviors, including learning and memory [50].

Postmortem analysis has shown lowered levels of BDNF in the brain tissues of people with Alzheimer's disease, although the nature of the connection remains unclear. Studies suggest that neurotrophic factors have a protective role against amyloid beta toxicity [112].

Researchers took a group of elderly Alzheimer's patients and studied them for 12 weeks [113]. Each participant underwent a test for mental function called the mini-mental status exam (MMSE), a standardized cognitive assessment used worldwide. They also underwent a blood test called highly sensitive C-reactive protein (hs-CRP), a powerful marker of inflammation. These tests were then repeated after 12 weeks.

The results were impressive [113]. The placebo group showed an increase in the inflammatory marker by 45%, while the probiotic group decreased the CRP by 18%. Over the 12 weeks, the placebo patients declined mentally. Their MMSE dropped from 8.47 to 8.00. The probiotic group improved their MMSE scores from 8.67 to 10.57. This study demonstrated that the probiotic administration for 12 weeks has favorable effects on mini-mental state examination (MMSE) score, malondialdehyde (MDA), serum high-sensitivity C-reactive protein (hs-CRP), markers of insulin metabolism, and triglyceride levels of the AD patients. These considerations led to establishing the term "psychobiotics" to highlight the potential effects of probiotics in the treatment of mental disorders [60]. Consistently, in a meta-analysis study, Kasińska and Drzewoski [60] reported a reduced homeostatic model of assessment for insulin resistance (HOMA-IR) and insignificant fasting plasma glucose (FGP) in probiotic-treated subjects. Mazloom et al. [109] also reported that probiotic supplementation had no significant effect on fasting blood glucose, markers of insulin metabolism, and lipid profiles.

The message here is that inflammation, which initiates or exacerbates all chronic illnesses including Alzheimer's disease, is dependent on the diversity and health of our gut bacteria. This, in turn, has major implications for brain health and function.

25.13 Autism

Autism is a condition in which intestinal microbiota is implicated. The onset of autism is often accompanied by intestinal dysfunction [79–81]. The first description of an association between autism and gastrointestinal syndrome began in 1971, with a report that 6 out of 15 autism patients had changed fecal character and defecation frequency [81].

Serotonin seeping from the second brain might even play some part in autism, the development disorder often first noticed in early childhood. Gershon has discovered that the same genes involved in synapse formation between neurons in the brain are involved in the alimentary synapse formation. "If these genes are affected in autism," he says, "it could explain why so many kids with autism have GI motor abnormalities" in addition to elevated levels of gut-produced serotonin in their blood [64]. About 95% of serotonin is produced by probiotics in the GI tract.

Food allergies, eczema, and asthma are associated with behavioral problems and neuropsychiatric disorders, including ADHD. Many children with autism spectrum disorders (ASD) present with GI systems and altered GI flora. ASD may involve brain inflammation. About 30% of children with ASDs have autoantibodies against brain proteins [42].

25.14 Parkinson's Disease

A high incidence rate of constipation is found in Parkinson's disease (PD) patients. Constipation can precede the onset of motor symptoms by more than 10 years [74].

Probiotics can efficiently reverse the impaired spatial learning and memory as well as synaptic transmission in diabetes mellitus [51]. It is demonstrated that other brain-related disorders, such as multiple sclerosis [52] and stress, are also influenced by probiotics [53]. In the levels of molecular mechanism, the microbiome is known to play a pronounced role in synaptic transmission. Numerous studies have shown capability of bacteria in producing neurotransmitters and neuromodulators including gamma-aminobutyric acid (GABA), norepinephrine, serotonin, dopamine, and acetylcholine [54]. Further, findings from germ-free animals indicated a decreased level of brain-derived neurotrophic factor (BDNF), important neurotrophic factor in neuronal growth and survival, and a reduced expression of some subunits of N-methyl-D-aspartate (NMDA) receptors [55]. GABA is the major inhibitory neurotransmitter in the CNS. Dysfunctions in GABA signaling are linked to anxiety, depression, and defects in synaptogenesis and cognitive impairments [57]. Also, the glutamatergic NMDA receptors are involved in the most important excitatory neurotransmission in the brain [58] and are engaged in the neural circuits involved in learning and memory. From these considerations, by contributing in neurotransmitter synthesis or receptor expression, probiotics might adjust the brain activity.

Accumulating evidence from experimental studies supports the hypothesis that via affecting inflammation, endocrine system, and neurotransmission, the gut microbiome takes a crucial role in the CNS function [59]. Accordingly, it is suggested that dysfunction of the neuroendocrine system, behavior, and cognition is correlated with gut microbiota dysbiosis [74].

25.15 Aging

We all know the brain changes as we age, as does the gastrointestinal tract. These changes, as well as a modification in lifestyle and decreased nutrition, increase the risk for infec-

tions, mental changes, physical impairments, and diminished cognitive abilities. The compromised microbiota in the elderly is associated with increased inflammation, also called inflammaging [11, 56, 74]. Inflammaging can also lead to decreased gut motility and constipation. Studies have illustrated an association between gut flora composition and cognitive processes, such as learning and memory. Additionally, intestinal microbiota contributes to the early development of normal social and cognitive behaviors [74].

Changes occurring in the microbiota during aging can have an impact on host health [74]. Notably, there is correlation between the relationship of falling microbial diversity and worsening frailty scores in elderly individuals. Additionally, drugs such as antibiotics, antacids, and H_2 receptor blockers can have profound negative effects on gut microbiota [74], all of which are more commonly used in the elderly as compared to a younger population. More than three-quarters of those aged 65 or older use at least one prescription medication, which can lead to unfavorable side effects on the GI tract [52]. For example, the use of opioids is linked to constipation [53], and the use of nonsteroidal anti-inflammatory drugs is linked with dysfunction in the GI defense system [54]. Furthermore, proton pump inhibitors, which are used to treat peptic ulcers, can trigger bacterial overgrowth of the upper GI tract through changes in the pH [17]. The use of broad-spectrum antibiotics can cause widespread disturbance in gut microbial composition and increase risk of *Clostridium difficile* infection, which in turn can reduce the biodiversity of gut microbiota [55]. As such, these medications can have implications on the microbiota-gut-brain-axis and influence CNS function.

Immunosenescence with chronic low-grade inflammation is characteristic in older age. This phenomenon, known as inflammaging, is distinguished by inflammation mediated by NK-kB and a loss of naïve CD4 T cells [56, 115]. A weakening of cell-mediated responses and reduction of the T-cell receptor repertoire have been shown in animal models upon aging [57]. In addition, clonal expansion of specific immune cells is impaired due to compromised cell division caused by a progressive shortening of telomeres through aging [58]. Notably, the GI microbiota of the elderly express a pro-inflammatory phenotype, as evidenced by a reduction in vitamin B12 synthesis and microbial reductase activity together with an increased incidence of DNA damage and immune compromise [50].

Indeed, inflammation is associated with a number of age-related diseases and neurodegenerative disorders, such as Parkinson's disease, Alzheimer's disease, multiple sclerosis, and motor neuron disease [60]. Claesson et al. showed that gut microbial composition and inflammation are directly linked to health outcomes [49]. They analyzed the microbiota composition and health outcomes in 178 patients living in different residences. Statistical analysis illustrated a clear difference in the microbial profiles depending on residence location, which significantly correlated with measures of nutrition, inflammation, frailty, and comorbidity. A decrease in community-associated microbiota and an increase in pro-inflammatory cytokines, as detected in long-stay hospital patients, were linked to increased frailty.

There is a decline in immune function in aging, and so microbiota-brain communication may be altered in the elderly, leading to changes in behavior. Supporting this is the fact that behavioral changes are observed in those with systemic infections as, similar to the gut, there is reciprocal communication between the CNS and the immune system [65]. Moreover, effects of gut microbiota and probiotics on inflammatory cytokines can have a direct effect on the brain.

Research groups have shown that gut microbes can also regulate the permeability of the blood–brain barrier (BBB), a highly selective barrier essential in protecting the brain from potential toxins [68]. Given that the function of both the BBB and microglia may deteriorate through age, these mechanisms are particularly relevant with regard to the role of microglia in elderly cognitive decline [69, 70]. Several epidemiological studies in elderly subjects have found links between diet and cognitive function [100]. In addition, chronic inflammation and a transformation in gut microbiota through age parallel a decline in cognitive function. The development of therapeutic strategies for diseases characterized by cognitive decline through alteration of the microbiota-gut-brain axis is an appealing possibility, particularly in the context of a global aging population [115]. However, much work still remains before this becomes a reality.

Decreased microbial diversity correlated with increased frailty, decreased diet diversity, health parameters, and increased levels of inflammatory markers. Individuals living in a community had the most diverse microbiota and were healthier as compared to those in short- or long-term residential care [74]. Firmicutes population drops with aging, while Bacteroidetes become the new dominant populations [74]. With a decline in Firmicutes, an increase in inflammatory diseases is found; this decline causes a decrease in immune response and reduced efficiency to digest. It was found that people at age 70 on average are still seen to have a similar biome of that of a 20- to 30-year-old; substantial changes are only seen within people who are older than 80 [74].

Deterioration in dentition, salivary function, digestion, and intestinal transit time may affect the intestinal microbiota with aging [74]. Aging is seen to negatively impact the microbiome, and the microbiome must be consistently maintained with a healthy diet to minimize the effects of aging [74].

In aging, BDNF is important as neuron morphology is critical in behavioral processes like learning and motor skills development [74]. BDNF levels have been shown to decrease in tissues with aging [74]. Studies using human subjects have found that hippocampal volume decreases with decreasing plasma levels of BDNF [74]. Like many other chemicals in the human body, aging decreases BDNF levels. This is why it takes the elderly longer to do complex tasks.

The relationship of BDNF to chronic illnesses and aging can be modified through a wide range of activities, nutrition, a healthy microbiome, and probiotics. Perlmutter rec-

25

Table 25.1 Strains of probiotics and which foods contain them

Lactobacillus plantarum	Sauerkraut, pickles, brined olives, kimchi, Nigerian ogi, sourdough, fermented sausage, stockfish, and some cheeses (such as cheddar)
Lactobacillus acidophilus	Yogurt kefir, miso, and tempeh
Lactobacillus brevis	Pickles, sauerkraut, and beer hop
Bifidobacterium lactis	Yogurt, miso, tempeh, pickled plum, pickles, kimchi, and many other forms of fermented and pickled fruits/vegetables that have not gone through the manufacturing process
Bifidobacterium longum	Yogurt, milk, fermented dairy foods, sauerkraut, and soy-based products

ommends five strains of probiotics to increase BDNF levels in the brain: *Lactobacillus plantarum, Lactobacillus acidophilus, Lactobacillus brevis, Bifidobacterium lactis,* and *Bifidobacterium longum* [114]. Table 25.1 lists the common foods to find these strains.

25.16 Fecal Transplants

While probiotics and antibiotics are generally known and available to treat gastrointestinal dysbiosis, fecal microbiota transplantation (FMT) has been rediscovered as a "new" way to restore gut microbiota. FMT is the administration of a solution of fecal matter from a donor into the intestinal tract of a recipient in order to directly change the recipient's gut microbial composition and confer a health benefit [74]. An early version of this practice was first documented in fourth-century China as "Yellow Soup." In some countries, maternal feces is inserted into the newborn's mouth to "jump-start" the colon. On June 17, 2013, the FDA approved FMT procedures for recurrent *Clostridium difficile* infection (CDI). There were zero documented serious side effects and there was a 92–95% success rate [74]. This strong interest is particular to patients with chronic gastrointestinal infections and inflammatory bowel diseases. Carefully screened donor stool is mixed with a saline solution. The solution is introduced into the GI tract via an NG tube, fecal enema, or oral capsules or during a colonoscopy. The "good" bacteria multiply and help flush out the *C. diff.* Bacteria. FMT reestablishes a balanced intestinal microbiota and results in impressive cure rates in patients with recurrent CDI. Standardization of FMT protocols and a randomized controlled trial are needed. FMT is likely to achieve widespread therapeutic benefit for a variety of diseases in the future [74].

FMT is currently approved by the FDA for the treatment of *Clostridium difficile* infection (CDI) with an IND (Investigational New Drug) application. FMT has also shown benefit in treatment of inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), and ulcerative colitis, all of which affect brain health [117]. Additionally, FMT has been linked to normalization of multiple sclerosis symptoms and improvement of chronic fatigue syndrome [74]. Neurological improvement was reported in one patient with Parkinson's disease [74].

25.17 Food Sources

Mood disorders can make everything in life seem impossible. Mood-altering pharmaceutical drugs are frequently prescribed. One out of every five adult Americans now uses these drugs in spite of their side effects and addictive properties [74].

It is important to look at other natural options that are effective to balance neurotransmitters and improve brain health. The microbiome and probiotics have been discussed. Removing sugar, refined grains, and processed foods is a good beginning. Specific tests for food allergies and gluten sensitivities are important to identify which foods need to be eliminated from the diet to decrease inflammation and the risk of autoimmune disease.

Eating fresh, organic, non-GMO whole foods are essential to a healthy diversified microbiome and brain health. Adding fermented foods is beneficial. As Hippocrates famously said, "Let food be thy medicine and medicine be thy food." The diversity of whole foods containing phytochemical, antioxidants, and anti-inflammatory properties has a significant impact on the gut microbiome and brain health. The lipopolysaccharide endotoxin (LPS) is particularly important in provoking depressive symptoms and disturbing blood sugar control [118]. Traditional dietary practices have shown a 38% reduction of LPS after 1 month, while the Western diet increases LPS elevation [70]. The health benefits of eating live beneficial bacteria are becoming more evident. Foods are now being produced that contain probiotic bacteria.

Fermentation of foods and beverages is an ancient practice. Superficially, it would seem obvious, given the brain's dependence upon nutrients for its structure and function (including the micronutrients and non-nutrient dietary antioxidants), that nutrition should be a target of research in mental health [66].

Fermented foods and foods that contain live bacteria have been used throughout the world for centuries. Foods are fermented to extend shelf life, improve taste, and increase nutrient value. Fermented foods are known to increase specific nutrients and the phytochemical content of foods. Research consistently shows that a diet consisting of traditional whole foods improves mental health. Fermented foods also support the growth of microbes such as *Bifidobacteria* and *Lactobacillus sp.* which, by themselves, have been shown to produce neurotransmitters [66, 115].

Traditional fermented whole foods are instrumental in the complex systems of mental, emotional, and brain health [66]. Research has shown this influence may be by virtue of

microbial actions, antioxidant and anti-inflammatory activity, reduction of intestinal permeability and decreasing LPS, improved glycemic control, nutritional support, lifestyle changes, and minimizing environmental toxins.

In addition to probiotics and fermented foods, other foods have also shown antidepressant properties, such as soy foods, cocoa, turmeric, green tea, coffee, blueberries, pomegranate, and honey [29–38]. Specific nutrients, such as magnesium, zinc, vitamin C, folic acid, and vitamin B12, have shown to decrease depressive symptoms [39–42]. Probiotics and the overall profile of the intestinal microbiota can influence tissue levels of mood-regulating minerals, such as magnesium and zinc [85, 86].

Since fatty acids seem to play an important role in shaping the gut microbiota metabolism, it is unsurprising that they have been considered as a dietary means to impede cognitive decline in aging. Human and animal studies on omega-3 polyunsaturated acids (n-3 PUFAs) have shed light on their neuroprotective roles through pathways of synaptic plasticity, neuroinflammation, and oxidative stress [106]. Recently, research has further suggested that through adult hippocampal neurogenesis, dietary choices, such as ingestion of n-3 PUFAs, can modulate brain structure and function throughout life [119].

25.18 Summary

The gut microbiota is a complex ecosystem which, in a healthy state, supports the major functions of the host by influencing metabolism, modulating the immune system, and protecting against pathogens.

The bidirectional communication and interaction between the ENS and CNS can support the body or cause disease depending on the diversity and health of the microbiome. The diseases not only affect the GI tract, through conditions like IBD, IBS, and colitis, or the CNS with mood disorders and neurological conditions, but they also have significant systemic impact and dysfunction.

Nagpal et al. clearly show that the gut microbiota is a promising target for preventative and therapeutic treatment of brain and mood disorders [115]. In the future, we may be able to use individual microbiome profiles in clinical practice to evaluate the current state and function of the gut. The use of prebiotics and probiotics, as well as fecal transplants, gives the clinicians a unique tool to treat chronic conditions.

UCLA's Mayer is doing work on how the trillions of bacteria in the gut "communicate" with enteric nervous system cells, which they greatly outnumber. His work with the gut's nervous system has led him to think that in the coming years, psychiatric treatment will expand to encompass the second brain in addition to the one atop the shoulders [74].

In terms of the potential treatment strategies, there is currently very limited research of the long-term effects of probiotics in human populations. Investigation of probiotics is further hindered by the varying quality control and efficacy of such a large family of compounds. Another area of research that is needed is the dose and the timing of probiotics and food. Carefully designed longitudinal clinical studies examining the microbial profiles of phenotype patients throughout life and the long-term effects of factors disturbing its compositions (e.g., via probiotics, antibiotics, dietary interventions) will be of great value to expand our knowledge of a promising area of research.

In 1907, Élie Metchnikoff probably never knew how exciting his discovery of the beneficial bacteria and phagocytes would be. Future research holds the potential of uncovering the intriguing connections between the gut microbiota and a multitude of chronic illnesses and neurological conditions.

» No disease that can be treated by diet should be treated with any other means. –Maimonides.

Learning Objectives

- Understand conventional cancer modeling and treatments and their limitations and failure points.
- Create a repertoire of integrative therapies.
- Recognize the complexity of creating an integrative cancer protocol.
- Fit together the puzzle pieces of human metabolism, cancer cell metabolism, tumor microenvironment, and integrative therapies.
- Learn to use nutritional therapies to complement conventional cancer care.

26.1 Introduction

26.1.1 What Is Cancer?

Cancer is not a singular disease but a group of highly complex diseases characterized by unregulated cell proliferation that share pathways and molecular and metabolic mechanisms for oncogenesis, invasive growth, and metastases.

26.1.2 Types of Cancer

Cancer can be grouped into two main categories: solid tumors and blood cancers. Within those two groups, there is differentiation based on the type of cell in which the cancer originates.

Solid Tumors: Abnormal Mass of Tissue – Benign or Malignant

- *Carcinomas* originate in the epithelial tissues, including the skin and tissues that line and cover the internal organs and body cavities.
- *Sarcomas* develop in connective tissues, including the bones, cartilage, tendons, muscle, and other fibrous tissues.
- *Central nervous system cancers* develop in the brain and spinal cord.
- *Lymphomas* begin in the lymphatic system, including the lymphatic glands and vessels, the spleen, and the bone marrow.

Hematological Cancers: Blood-Forming Tissue Cancers

- *Leukemias* originate in the blood and bone marrow.
- *Multiple myeloma*
- *Lymphoma*

26.1.3 Statistics of Cancer

Despite medical science shining a tremendous amount of light on the growth mechanisms of these cancers, we have not yet made significant strides in conquering this disease. According to the American Cancer Society, in 2019, there will be an estimated 1,762,450 new cancer cases diagnosed, more than 4800 new cases daily, and approximately 606,880 cancer deaths [1] (▶ Boxes 26.1 and 26.2).

Box 26.1 Statistics List

- Three most common cancers diagnosed in men: prostate, lung, and colorectal
- Three most common cancers diagnosed in women: breast, lung, and colorectal
- Second most common cause of death among children aged 1–14 years in the US is cancer
- Lifetime probability of being diagnosed with cancer: 39.3% for men and 37.7% for women
- Based on data from Ref. [1]

Box 26.2 5-Year Relative Survival Rate

- Highest:
  - Prostate 98%
  - Melanoma of the skin 92%
  - Female breast cancer 90%
- Lowest:
  - Pancreas 9%
  - Liver 18%
  - Esophagus 19%
  - Lung 19%
  - Based on data from Ref. [1]

One out of every two males and one out of every three females can expect to be diagnosed with cancer within their lifetimes. Certain cancers have seen significant improvement in relative survival and cure rates, such as childhood leukemia, while the incidence of other cancers and their mortality rates are increasing. The American Association for Cancer Research released some unexpected projections for a shift in cancer statistics:

"Cancer incidence and deaths in the United States were projected for the most common cancer types for the years 2020 and 2030 based on changing demographics and the average annual percentage changes in incidence and death rates. Breast, prostate, and lung cancers will remain the top cancer diagnoses throughout this time, but thyroid cancer will replace colorectal cancer as the fourth-leading cancer diagnosis by 2030, and melanoma and uterine cancer will become the fifth and sixth most common cancers, respectively. Lung cancer is projected to remain the top cancer killer throughout this time period. However, pancreas and liver cancers are projected to surpass breast, prostate, and colorectal cancers to become the second and third leading causes of cancer-related deaths by 2030, respectively" [2].

These statistical analyses are done to determine the allocation of research funding as well as the relative effectiveness of the conventional routes of cancer treatment: chemotherapy, radiation, surgery, hormone therapy, immunotherapy, and targeted therapies.

26.1.3.1 The Functional, Integrative, Holistic, and Nutritional Perspective

A deeper holistic look at these statistics can illustrate shifts in causality, such as toxic exposures, infection [3], and dietary deficiencies [4]. This perspective is an opportunity to create change.

The statistics do not tell the story of the bio-individual aspects of the whole person. Lifestyle, exposure to toxins and pathogens, diet, emotional wellness, use of supplements, physical activity, exposure to EMF radiation, preconception history, all of these affect the molecular and epigenetic changes that can initiate or prevent the growth of cancer in the body.

On his deathbed, Louis Pasteur famously recanted his germ theory and said, "Bernard is correct. I was wrong. The germ is nothing. The terrain is everything." Claude Bernard's work aligned with that of Antoine Bechamp who originated the terrain theory [5]. Bechamp felt that disease resulted when microbes "changed form, function and toxicity" based on the terrain of the host.

» The constancy of the internal environment is the condition for a free and independent life. –Claude Bernard [5]

Cancer is the same. Conventional treatment focuses on the "germ or microbe" (tumor). Integrative care focuses on both the germ and the terrain (the health of the person).

Conventional therapy is effective at surgical debulking cytoreduction (surgically reducing tumor bulk), with or without chemotherapy and/or radiation. It does not address protecting healthy cells during treatment. Unfortunately, many therapies leave the patient with the risk of secondary cancers due to the toxicity of treatment, depression of the immune system causing a host of issues, the most dangerous of which is sepsis, as well as the risk of recurrence or metastasis of the original cancer in an enriched state. Enriched cancer cells arise when tumor bulk is reduced, but the stem cells are not eradicated. These remaining "enriched" stem cells then become resistant to future treatment, akin to MRSA in the bacterial world.

The ability of the body to prevent the growth of cancer and the potential of the immune system to conquer it are our most overlooked weapon in the war on cancer. Factors that can be optimized to create a body that can effectively engage in this battle include lifestyle, diet, honoring bio-individual needs, consuming anti-inflammatory foods that nourish the tissues and cells, reducing the toxic burden of the body, and attending to emotional and energetic imbalances [4, 6]. This improves clinical outcome and quality of life and aids in the management of conventional treatment. These are exactly the efficacy endpoints of any cancer treatment.

When considering how to utilize nutrition and supplementation in complementary and adjunctive cancer therapy, several things should be considered:

- Anti-inflammatory diet: Any biologically contraindicated foods should be avoided, such as gluten, dairy, eggs, lectins, nightshades, or other common allergens and inflammatory triggers, based on the needs of the individual.
- Targeted supplementation based on a nutritional and clinical assessment of any nutrient deficits (e.g., vitamin D, zinc, methyl nutrients, minerals) is important to optimize immune function until goal test markers are reached and maintained.
- Herbal therapies: Certain herbs and roots have gained a reputation as cancer fighters but should be examined in the setting of any underlying disease as well as drug regimens. For instance, turmeric/curcumin [6] being contraindicated when used in combination with certain chemotherapy drugs such as camptothecin, mechlorethamine, doxorubicin, or cyclophosphamide in the treatment of breast cancer [7–10].
- Detoxification support: Cytochrome pathways (discussed below) should be checked for inhibition or induction potential of food, herb, and drug combinations. Some of these situations are synergistic, while others are potentially harmful.

Moving forward, our goal should be to utilize the ability of certain foods and herbs to positively impact quality of life, sensitize cancer cells, protect healthy cells, and manipulate the tumor microenvironment to the benefit of the patient. If a substance can increase the amount of time that a chemotherapeutic agent is held in the body, while positively affecting disease markers, it may be possible that the drug dose can be reduced while simultaneously creating a positive patient outcome due to reduced side effects of the drug. This approach may make dose reductions of both chemo and radiation possible without a loss of efficacy, consequently allowing for potentially fewer side effects, better quality of life, and extension of treatment potential by resolving dose-limiting toxicities and time to resistance.

Phytonutrition is the therapeutic potential of the colorful pigments in plants to act as modifiers of physiological function with growing evidence related to modulation of carcinogenesis [10]. For the nutritionist, understanding the functional parameters that impact the absorption and utilization of these compounds will allow for their use to be optimized in specific interventions. Although most plants contain significant amounts of phytochemicals, certain groups are higher in lycopenes, such as red and pink fruits and vegetables, or the isothiocyanates found in cruciferous vegetables. An awareness of the evidence-based research specific to the impact of specific phytonutrients on certain cancers can create a significant impact on dietary recommendations for patients. This can enable the creation of integrative food- and botanical-based nutrition protocols for prevention and adjunctive therapies. The same theory can be applied to the metabolic function of fats and proteins and their physiological effects. Whole food and herbs can truly perform as complementary medicine [10].

Fig. 26.1 Graphic Hallmarks of Cancer (Courtesy of Cynthia Henrich)

26.2 Mechanisms of Oncogenesis and Metastases

The wealth of research on the mechanisms of cancer can be used to reverse engineer similar effects utilizing diet, lifestyle, and natural therapies either alone or integrated with conventional therapies. This integration can improve quality and length of life for patients while simultaneously contributing to their whole-body wellness. First, we must examine the underlying framework of mechanisms that enable the transformation of a healthy cell into a malignant cell capable of metastasizing to distant sites. According to the conventional model, the mechanisms are as follows and should each be viewed as an opportunity to affect the outcome with integrative strategies:

26.3 The Hallmarks of Cancer

Although cancer is a collection of highly complex diseases, cancer cells demonstrate a set of distinct traits across tumor types that enable them to reproduce and metastasize, according to conventional theories. Drs. Hanahan and Weinberg began to elucidate and expand on these traits [11]. Research has emerged of late that cancer cell metabolism and stem cells are not following the previous dictums and challenging these hallmark traits. Tumors exhibit another dimension of complexity in that they contain a repertoire of recruited, apparently normal cells that contribute to creating the tumor microenvironment (Fig. 26.1) [11].

26.4 Current Conventional Medical Treatment

Chemotherapy, radiation, surgery, immunotherapy, hormone therapy, and targeted therapies have been designed to interrupt some point in the process of transformation of the cell into malignancy or to prevent that event from recurring. To offer individualized treatment options, histological compatibility and oncotyping tests have been developed to examine the genetics of a patient's tumor and their best response to treatment options. This can help to identify growth mechanisms and potentially chart a course for drug therapy.

26.4.1 Chemotherapy and Targeted Therapies

According the SEER*Rx Interactive Antineoplastic Drugs Database on the National Cancer Institute website, there are currently 1867 drugs that can be combined into 510 potential regimens for conventional cancer treatment [12].

Gaining an understanding of the classes of chemotherapeutic agents and their typical side effects, such as impact on platelets and cytochrome pathways, can make it easier to determine functional and genomic interactions with supplements and food. This will enable the practitioner to more carefully construct a dietary and botanical protocol that is most useful to the patient. There are several types of chemotherapy, each of which can be administered via oral, intravenous, intraperitoneal, transdermal, or implantable routes depending on the drug and cancer:

26.4.1.1 Alkylating Agents

Alkylating agents were one of the earliest classes of drugs developed to treat cancer. They work by chemically altering the DNA of a cancer cell by adding an alkyl group to directly modify DNA bases or form cross-links to prevent replication and/or induce apoptosis. These drugs are particularly devastating to the rapidly dividing cells that line the gut. Tremendous damage to the mucosal barrier impacts digestion and absorption, as well as frequently inducing side effects such as diarrhea and dehydration that can limit or end a course of chemotherapy [13].

Alkylating agents are most active in the resting phase of the cell. These types of drugs are cell-cycle nonspecific. There are several types of alkylating agents used in chemotherapy treatments:

- Mustard gas derivatives: Mechlorethamine, cyclophosphamide, chlorambucil, melphalan, and ifosfamide
- Ethylenimines: Thiotepa and hexamethylmelamine
- Alkyl sulfonates: Busulfan
- Hydrazines and triazines: Altretamine, procarbazine, dacarbazine, and temozolomide
- Nitrosoureas: Carmustine, lomustine, and streptozocin. Nitrosoureas are unique because, unlike most types of chemo treatments, they can cross the blood–brain barrier. They can be useful in treating brain tumors.
- Metal salts: Carboplatin, cisplatin, and oxaliplatin (► Box 26.3).

Box 26.3 Nutritional Therapies That Can Be Used to Preserve the Mucosal Barrier Function During Treatment

- Glutamine (cabbage is rich in the amino acid L-glutamine)
- Zinc carnosine
- Mastica
- Butyrate (ghee is rich in butyric acid)
- Immunoglobulin-rich colostrum
- Probiotic and prebiotic foods
- Mushrooms such as Cordyceps and Ganoderma
- Plant-based protein powders
- Elemental diet therapy
- Turmeric
- Ginger
- Herbs such as slippery elm, licorice root, aloe, marshmallow root and chamomile

26.4.1.2 Plant Alkaloids

Plant alkaloids are chemotherapy treatments derived from certain types of plants. The vinca alkaloids are made from the periwinkle plant (*Catharanthus roseus*). The taxanes are made from the bark of the Pacific Yew tree (taxus). The vinca alkaloids and taxanes are also known as antimicrotubule agents. The podophyllotoxins are derived from the mayapple plant. Camptothecin analogs are derived from the Asian "Happy Tree" (*Camptotheca acuminata*). Podophyllotoxins and camptothecin analogs are also known as topoisomerase inhibitors, which are used in certain types of chemotherapy. The plant alkaloids are cell-cycle specific. This means they attack the cells during various phases of division.

- Vinca alkaloids: Vincristine, vinblastine, and vinorelbine
- Taxanes: Paclitaxel and docetaxel
- Podophyllotoxins: Etoposide and teniposide
- Camptothecin analogs: Irinotecan and topotecan

26.4.1.3 Antitumor Antibiotics

Antitumor antibiotics are chemotherapeutic treatments made from natural products produced by species of the soil fungus, *Streptomyces*. These drugs act during multiple phases of the cell cycle and are considered cell-cycle specific. This class of drugs will have a significant impact on the diversity of the microbiome that must be addressed during and post-treatment. There are several types of antitumor antibiotics:

- Anthracyclines: Doxorubicin, daunorubicin, epirubicin, mitoxantrone, and idarubicin
- Chromomycins: Dactinomycin and plicamycin
- Miscellaneous: Mitomycin and bleomycin

26.4.1.4 Antimetabolites

Antimetabolites are types of chemotherapy treatments that are very similar to normal substances within the cell. When the cells incorporate these substances into the cellular metabolism, they are unable to divide. Antimetabolites are cell-cycle specific. They attack cells at very specific phases in the cycle. Antimetabolites are classified according to the substances with which they interfere.

- Folic acid antagonist: Methotrexate
- Pyrimidine antagonist: 5-fluorouracil, floxuridine, cytarabine, capecitabine, and gemcitabine
- Purine antagonist: 6-mercaptopurine and 6-thioguanine
- Adenosine deaminase inhibitor: Cladribine, fludarabine, nelarabine, and pentostatin

26.4.1.5 Topoisomerase Inhibitors

Topoisomerase inhibitors are types of chemotherapy drugs that interfere with the action of topoisomerase enzymes (topoisomerase I and II). During the process of chemotherapy treatments, topoisomerase enzymes control the manipulation of the structure of DNA necessary for replication.

- Topoisomerase I inhibitors: Irinotecan and topotecan
- Topoisomerase II inhibitors: Amsacrine, etoposide, etoposide phosphate, and teniposide

26.4.1.6 Miscellaneous Antineoplastics

Several useful types of chemotherapy drugs are unique:

- Ribonucleotide reductase inhibitor: Hydroxyurea
- Adrenocortical steroid inhibitor: Mitotane
- Enzymes: Asparaginase and pegaspargase
- Antimicrotubule agent: Estramustine
- Retinoids: Bexarotene, isotretinoin, tretinoin (ATRA)

Targeted therapies have been designed to target pathways outside of the common feature of cancer cells to be able to divide rapidly. Because many normal cells in the human body also divide rapidly, multiple side effects may unfortunately occur that can limit treatment and cause significant damage or morbidity to the person [14, 15].

The different types of targeted therapies are defined in three broad categories. Some targeted therapies focus on the internal components and function of the cancer cell. The targeted therapies use small molecules that can get into the cell and disrupt cellular function, resulting in apoptosis. There are several types of targeted therapy that focus on the inner parts of the cells, while other targeted therapies focus on receptors that are on the outside of the cell known as monoclonal antibodies.

Antiangiogenesis drugs target the blood vessels that supply oxygen to the cells, ultimately causing the cells to starve. Specifically, this class of drugs is designed to stop the formation of new blood vessels. There is some research indicating that this particular hallmark of cancer may need to be revisited because certain tumors seem to have the capability to co-opt existing blood vasculature. This can account for resistance to antiangiogenic drugs and may distinguish which tumors may be susceptible to therapy [16].

Monoclonal antibodies are a targeted cancer therapy that use an antibody to specifically target an antigen on the surface of a cancer cell. This lock-and-key function causes less toxicity to healthy cells but is limited to the cancers in which antigens and their respective antibodies have been identified. One way the immune system attacks foreign substances in the body is by making large numbers of antibodies. An antibody is a protein that sticks to a specific protein called an antigen. Antibodies circulate throughout the body until they find and attach to the antigen. Once attached, they can recruit other parts of the immune system to destroy the cells containing the antigen. The following are monoclonal antibodies: alemtuzumab, gemtuzumab ozogamicin, rituximab, trastuzumab, and ibritumomab tiuxetan.

Other targeted therapies include the following:

- Signal transduction inhibitors:
  - Imatinib mesylate (protein-tyrosine kinase inhibitor)
  - Gefitinib (epidermal growth factor receptor tyrosine kinase inhibitor, EGFR-TK)
    - Tyrosine kinases are a family of enzymes which catalyze phosphorylation and regulate biological processes like growth, differentiation, metabolism, and apoptosis of cells.
  - Cetuximab (epidermal growth factor receptor)
  - Lapatinib (epidermal growth factor receptor (EGFR))
  - Human epidermal receptor type 2 (HER2) tyrosine kinase inhibitor
    - Anti-EGFR therapies can inhibit the activation of the EGFR signaling pathway in cancer cells which has been linked to increased cell proliferation, angiogenesis, metastasis, and decreased apoptosis.
- Biologic response modifier agent: Denileukin diftitox
- Proteasome inhibitor: Bortezomib [17]

26.4.2 Radiation

Radiation therapy uses high-energy X-rays, gamma rays, electron beams, or protons to make small breaks in the DNA of cells or to create free radicals within the cells that will prevent replication and cause cancer cell death. The radiation may be delivered as external beam radiation therapy or as internal radiation therapy, also known as brachytherapy, via radioactive material placed in the body near the tumor. Systemic radiation therapy uses radioactive substances, such as radioactive iodine, to travel throughout the body to kill cancer cells. Approximately half of all cancer patients receive some type of radiation therapy sometime during the course of their treatment.

Radiation use is generally limited by late-onset adverse events that can occur during treatment or even months or years later. Secondary cancers, inflammatory conditions such as pneumonitis and proctitis, and radiation fibrosis, an irreversible condition characterized by increased connective tissue stiffness and loss of tissue function at the irradiated site, are a few of the typical outcomes of radiation therapy.

It may be possible to predict who may be at risk of radiation-induced fibrosis via genetic markers and methylation status. The application of this research may include dietary modification and supplement use to optimize methylation status, restore nutritional insufficiencies, monitor hypercoagulation (fibrinogen, platelets, and d-dimer markers), and mitochondrial protection [18].

Radiation has been found to create more cancer stem cells (CSC) that are resistant to treatment. Recent evidence indicates that radiation converts non-stem cancer cells into cancer stem cells, which exhibit similar radioresistance to intrinsic CSCs (cancer stem cells which are resistant to treatment and cause relapse and metastasis) [19]. A possible mechanism of cancer resistance to radiation may be through CSCs that should be killed by radiotherapy but are able to survive radiotherapy. After radiation-induced stresses disappear, these newly generated CSCs, together with the intrinsic CSCs, contribute to the relapse and metastasis of cancer [19].

An alternative to conventional radiation therapy is proton therapy. Proton therapy is an advanced form of radiation therapy that uses protons—positively charged atomic particles—instead of the photons used in standard X-ray radiation therapy. With proton therapy, doctors can precisely target the tumor while minimizing damage to the surrounding healthy

tissue. Unlike X-ray radiation, such as intensity-modulated radiation therapy [IMRT], protons deposit much of their radiation directly in the tumor and then stop. For example, in prostate cancer, proton therapy eliminates about 60% of excess radiation delivered to healthy tissues surrounding the prostate compared to IMRT. Proton therapy can treat recurrent tumors in patients who have already received traditional forms of radiation, reduce the incidence of short- and long-term side effects, and incur a lower incidence of secondary tumors. This may potentially allow the use of higher, more effective doses of radiation.

26.4.3 Surgery

Surgical resection of a tumor with clear margins and negative lymph findings is the single best predictor of survival. Many conventional therapies are aimed at reducing tumor bulk in order to perform surgery. If tumor debulking surgery is not optimal, vascular endothelial growth factor (VEGF) may increase, which could increase angiogenesis.

26.5 Terrain Versus Cancer

Perhaps the most overlooked aspect in standard cancer care is the biological and emotional condition of the person. Science is doing an excellent job at uncovering pathways, genetics, and mechanisms of the genesis and growth of cancer, but because the focus is on drug development, the epigenetic impact of nutrition and lifestyle on these processes is largely ignored. The research, however, is extremely useful in terms of reverse-engineered nutrition and lifestyle solutions.

Consider the old argument of germ versus terrain referring to pathogenic infectious organisms and apply the concept to oncology. Enormous potential exists in the unexplored realm of cancer versus terrain. Use the information gleaned from the laser-focused study of cancer cells and tumors to reduce the manifestation of cancer by optimizing the cellular processes of the body through intensive bio-individually appropriate nourishment and detoxification. Imagine accounting for this within the framework of cancer statistics. We account for age, but none of the other driving factors that enable cancer to develop; or in the survivors, where radical lifestyle changes may dramatically shift where they fit in (or now defy) the survival statistics.

It is the epitome of the poem, "The Road Not Taken," by Robert Frost:

> *Two roads diverged in a wood, and I—*
> *I took the one less traveled by,*
> *And that has made all the difference.*

Dietary epigenetics, medical nutrition therapy, lifestyle medicine, circadian medicine, and detoxification protocols to optimize the human terrain will shift the entire way that we approach cancer prevention, treatment, and survival. These methods will enable practitioners to optimize the wellness of the patient, thereby creating a strong foundation for the body to withstand treatment, balance immune function, and tailor a dietary strategy that is ideal for the patient throughout different stages of treatment and recovery.

26.6 Optimization and Protection

The inclusion of the appropriate balance of macronutrients, saturation of micronutrients, and exclusion of harmful and toxic anti-nutrients is the core of cellular optimization. This allows the enzyme-driven processes of methylation, acetylation, phosphorylation, ubiquitination, and sumoylation to appropriately regulate cellular function and epigenetic expression, thereby enabling optimal mitochondrial metabolism.

Mitochondria are the primary source of energy for the body and dealing with mitochondrial metabolism can be thought of as two sides of a coin: optimize function and prevent dysfunction. The approach to this is multifaceted: provide the necessary nutrients, precursors, and cofactors; optimize liver function and detoxification; and determine bio-individual requirements for certain vitamins, conditionally essential nutrients, amino acids, and fatty acids to ensure optimal enzymatic function and genetic expression.

The importance of optimal mitochondrial function cannot be overstated. It is implicated in stem cell self-renewal, cardiomyocyte regeneration, neural stem cell survival [20], skeletal and heart muscle function and repair, neurological inflammation [21], cellular senescence [22], telomere shortening [23], oncogene initiation, and more.

26.7 Synergistic Therapies

Synergistic therapy in integrative oncology means that a particular substance or action will protect healthy cells while enabling another therapy to work more effectively. This can potentially enable the reduction of a chemotherapy drug dose through enhanced chemosensitivity, thereby reducing toxicity and side effects, or even dramatically shift an outcome by tapping into the power of diet on biology.

Synergistic therapies [24, 25] can be administered or performed concurrently with standard therapies, or they can be cycled throughout the regimen based on drug metabolism, pharmacokinetics, and pharmacogenetics. Each individual therapy, food, herb, vitamin or mineral, exercise, or mindfulness practice needs to be assessed on an individual basis, taking into consideration the regimen being administered as well as the bio-individual nature of the person. For instance, certain genetic markers or liver metabolism factors can create a need for optimization of

methylation or adjustment for more rapid clearance of a substance through the cytochrome pathways. There is more and more information correlating phytonutrients and supplements with these metabolic pathways. It is helpful to check which pathway may be affected and cross-check that with the regimen and the patient.

Cytochrome P450 enzymes are essential for the metabolism of many medications [26]. Although this class has more than 50 enzymes, six of them metabolize 90% of drugs, with the two most significant enzymes being CYP3A4 and CYP2D6. Genetic variability (polymorphism) in these enzymes may influence a patient's response to commonly prescribed drug classes, including beta-blockers and antidepressants. Cytochrome P450 enzymes can be inhibited or induced by drugs, resulting in clinically significant drug-drug interactions that can cause unanticipated adverse reactions or therapeutic failures [26].

Drug metabolism is not limited to liver biotransformation but also occurs through the kidney, intestinal cells, lungs, central nervous system, gastric mucosa, prostate, and, in some cases, even the skin.

Because many regimens include premedication to alleviate side effects or to act as adjuvant therapy, the metabolism/drug interactions can become even more complicated. Referring to a clinical pharmacology P450 drug interaction table such as the one from the Indiana University School of Medicine can be helpful, but the complex nature of multidrug metabolism can make the use of therapeutic doses of food or supplements an incredibly complex situation [27].

26.8 Emotional Aspect of Cancer

Psycho-oncology explores how trauma and prolonged chronic stress can play a part in oncogenesis. It is extremely common when working with cancer patients for them to share that an emotional conflict or trauma occurred approximately 18–24 months prior to their diagnosis. The processing of a trauma of this nature can impact deep sleep patterns and the production of melatonin. Melatonin is primarily synthesized by the pineal gland and is a natural antioxidant with immune-enhancing properties. Melatonin production declines with age and may be one of the major contributors to immunosenescence and cancer genesis [28].

Among the various functions attributed to melatonin in the control of the immune system, antitumor defense assumes a primary role [28]. The nighttime physiological surge of melatonin in the blood or extracellular fluid has been suggested to serve as a natural restraint for tumor initiation, promotion, and/or progression. Melatonin was demonstrated to be oncostatic for a variety of tumor cells like breast carcinoma, ovarian carcinoma, endometrial carcinoma, human uveal melanoma cells, prostate tumor cells, and GI tumors [28].

Melatonin is also involved in genetic expression, primarily with the genes controlling the cell cycle, adhesion, and transport. It specifically impacts mitochondrial gene expression. Melatonin increases the production of cytokines IL-2, IL-6, IL-12, and IFN-gamma from lymphocytes and monocytes, which then increases the amount of natural killer cells.

The waterfall effect of stress reaches well past melatonin. As cortisol levels remain inappropriately elevated over time, stress is placed on the adrenal glands and adrenaline production. Adrenaline is required to stimulate the G-protein for the oxidative phosphorylation cycle of mitochondria, producing ATP by converting glucose in the Krebs citric acid cycle. As adrenaline production is depleted, the conversion of glucose to ATP is inhibited, and instead the glucose ferments and creates lactic acid as a by-product inducing cellular DNA and mitochondrial mutations.

Circadian rhythms and traditional Chinese medicine (TCM) both correlate time with physical balance and energy [29]. As described, in TCM, there are 14 major meridians that conduct the flow of Qi throughout the body. Twelve of these meridians make up the 24-hour clock, representing 2 hours each. The energy is constantly flowing through all of these meridians throughout the 24 hours, with each meridian having a 2-hour period of time as the primary meridian. The meridian reflects the energy of its associated organ, but also it reflects other processes in us: thoughts, emotions, colors, sounds, seasons, and even spiritual aspects [29]. The meridians are coupled in pairs of Yin (receiving energy) and Yang (expressing energy) of one of the five elements—earth, metal, water, wood, and fire [29].

So, for instance, recurring insomnia at the same time each night, or a physical complaint at the same time each day, may correlate to an emotion or issue that is causing a disruption or stagnation in the life force energy or chi. Examples include the following:

- Liver-gallbladder: anger, resentment, and frustration
- Heart-small intestine: emotional instability, discontent, lack of focus, and heartbreak
- Spleen-stomach: worry and lack of empathy
- Lung-large intestine: sadness and unresolved grief
- Kidney-urinary bladder: fear, abandonment, and anxiety

Often, the emotion of the initiating trauma will line up with an illness manifesting in the corresponding organ pair. This type of work is a beautiful opportunity to walk the border between physiology and emotion, navigating the Rivers of Qi.

If you can recall the moments of childhood where hours were spent so busy, happy, and content that one might forget to eat unless called, you can see that emotional balance and joy are sustenance in their own right. Addressing these emotional needs or imbalances by simply acknowledging their existence is often enough to create awareness and initiate the healing process. Nourishing the spirit can further that healing (▶ Box 26.4).

Box 26.4 Nutritional and Lifestyle Strategies for Emotional Support

- Optimize sleep
  - Melatonin and foods rich in melatonin
  - Theanine (found in green tea)
  - Magnesium
  - Apply a blue light filter on devices to mimic sundown.
  - Sleep in a completely dark room.
  - No caffeine
- Mindfulness and meditation
- Yoga
- Deep breathing
- Acupuncture
- Exercise
- Spiritual practices
- Clean diet free of chemicals

26.9 Lifestyle Detoxification

From a holistic perspective, what you avoid and the relationships that influence you are as important as what you include in your life. Every action, product, food, movement, emotion, and breath is an opportunity to positively impact your wellness. Sharing this concept with patients will empower them to gain a sense of control and to participate in their healing process.

Detoxification is such an important aspect of wellness, both in the material and emotional world. Removing existing toxins and avoiding potential toxins reduce the environmental burden, making it easier for the body to focus on healing. Cleaning up the diet, personal and household products, and the emotional realm are the first steps toward wellness (see ▶ Chap. 13).

26.9.1 Avoid or Remove?

Antigenic triggers Based on the bio-individual needs of a patient, eliminate any potential allergens that might not have been previously considered: gluten, dairy, corn, eggs, soy, and nightshades.

Mold Any mold exposure should be remediated or avoided. This is extremely toxic and immunosuppressive.

Amalgam fillings Although controversial and especially when considered during cancer treatment, amalgam fillings may be removed by a biological dentist who uses the right precautions and detoxification procedures. The decision may depend on the degree of deterioration of the fillings.

Plastics as endocrine disruptor compounds (EDCs) Plastic wrap, plastic water bottles, and even the bisphenol-free plastics have been found to leach EDCs. Patients should be advised to never heat food in those containers but rather transfer it to a safe container for heating.

Chemicals Scented products, such as air fresheners and dryer sheets, cleaning products, beauty and personal products, detergents, and soaps that are commonly found in most households should be avoided. Styrofoam in packaging, drinking cups, and food containers should be avoided. Pesticides, fertilizers, and herbicides are commonly applied to crops, and patients undergoing treatment should be encouraged to purchase organic, if possible. Check labels of packaged food and personal products to eliminate chemical exposures, preservatives, and artificial ingredients and sweeteners. Perfluorinated alkylated substances (PFAS) such as in Teflon-coated clothing or cookware, fire retardant-coated clothing, furniture, and carpeting should be avoided.

EMF exposure Be conscious of the use of electronic devices in the evening as it will impact melatonin production. Leave your phone outside of your bedroom or set to airplane mode overnight. Do not carry the device close to your body and use air tube headsets to reduce EMF exposure to the head and neck area.

Microbiome disruptors Meat, fish, or animal products that are laden with hormones, antibiotics, and chemically altered feed have the potential to disrupt not only the animal microbiome but also the consumers. Fat stores from the animals contain even higher concentrations as these chemicals are lipophilic and of great concern.

High-glycemic foods Fast food, processed food, foods high in sugar, alcohol, and high-fructose corn syrup are not nutritious options for patients undergoing cancer treatment. Processed foods of low-nutrient density, such as high calorie, low nutrient density liquid enteral food and other chemically laden foods, sugar, undesirable fats, synthetic vitamins, and casein-filled anti-nutritive beverages, should be avoided and alternate recommendations made.

IV nutrition Intravenous nutrition is the fastest, most assured way of reaching clinically effective levels of the administered substances in the body. Deficiencies of stomach acid and enzymes or inflammatory gut conditions may inhibit the absorption of a variety of nutrients. IV nutrition bypasses the digestive tract and delivers the nutrients directly into the bloodstream for more direct access to the organs and tissues in need. It can also work to increase energy levels and reduce side effects and is excellent for recovery posttreatment. Careful follow-up of vitamin and mineral levels are needed to ensure safety.

Linus Pauling, one of the fathers of orthomolecular medicine and the Linus Pauling Institute of Oregon State University [30], have laid the foundation for evidence-based research on micronutrients. Several physicians and clinics have contributed vast stores of knowledge to this story, including Jeanne Drisko, MD [31], Dwight McKee, MD [32], Paul Anderson, ND and Mark Stengler, ND [33], and Keith Block, MD [34].

The NIH National Cancer Institute, Office of Cancer Complementary and Alternative Medicine (OCCAM) has references for clinical trials as well as specific drug integration [35]. They report that laboratory studies of high-dose vitamin C have shown decreased cell proliferation in prostate, pancreatic, hepatocellular, colon, mesothelioma, and neuroblastoma cell lines and that patients report improved quality of life and decreased cancer-related side effects. Refer to the Human Clinical Studies page for more examples and ongoing clinical trials [36].

Intravenous therapies may include:

- Ascorbic acid (a G6PD test should be run prior to administration as fatal hemolysis can occur if a patient has glucose-6-phosphate dehydrogenase deficiency; also contraindicated is renal insufficiency) [37]
- Glutathione
- B vitamins
- Magnesium
- Potassium
- Lipoic acid
- L-carnitine
- Minerals

Mixtures of various ingredients known as cocktails are also created to specifically target particular issues.

One combination of alpha lipoic acid (ALA), low-dose naltrexone (LDN), and vitamin D has been shown in case reports to have potential promise in the treatment of stage 4 adenocarcinoma of the pancreas [38, 39]. The authors described the long-term survival of a man with pancreatic cancer with metastases to the liver, treated with intravenous ALA and oral LDN without any adverse effects, and was alive and well 78 months after initial presentation. Three additional pancreatic cancer case reports were presented. At the time of the report, the first patient was alive and well 39 months after presenting with adenocarcinoma of the pancreas with metastases to the liver. The second patient who presented with the same diagnosis was treated with the ALA/LDN protocol, and after 5 months of therapy, PET scan demonstrated no evidence of disease. The third patient, in addition to his metastatic pancreatic cancer, had a past medical history of B-cell lymphoma and prostate adenocarcinoma. After 4 months of the ALA/LDN protocol, the CT/PET scan demonstrated no evidence of disease [38].

26.9.2 Sepsis

Sepsis is a common end-of-life occurrence in oncology [40]. Marik et al. will soon publish in *Chest* their own small before-and-after unblinded cohort study, born of an anecdote that should intrigue any intensivist: Three patients with "fulminant sepsis ... almost certainly destined to die" from shock and organ failure, were infused with vitamin C and moderate-dose hydrocortisone out of desperation. All three patients recovered quickly and left the ICU in days "with no residual organ dysfunction."

Inspired by that experience, they went on to enroll and treat 47 septic patients with a cocktail of 1.5 g vitamin C IV every 6 hours, hydrocortisone 50 mg IV every 6 hours, and thiamine 200 mg IV every 12 hours (thiamine inhibits oxalate production and has potential benefits in septic shock). Controls were 47 patients matched in baseline characteristics. Hospital mortality was 4 of 47 (8.5%) in those treated with the cocktail, compared to 19 of 47 (40%) in those not. Vasopressors were weaned off in all cocktail-treated patients, usually in <24 hours (vs. 4 days for the controls). Renal function reportedly improved in all patients with acute kidney injury [41].

Intravenous nutrition therapy should be a first-line as well as an integrative therapy consideration for every patient. Riordan Clinic has developed a compendium of evidence-based research when deciding on treatment [42].

26.9.3 Integrative and Functional Nutrition

The impact of good nutrition in cancer prevention or as part of an integrative treatment program is well established. Food-based nutrients are capable of preventing cellular DNA damage from carcinogenic environmental factors. The correct dietary choices can ensure proper detoxification, immune system function, and metabolic function, reduce inflammation, increase longevity and quality of life, and minimize side effects of conventional treatment. The challenge lies more in breaking down the information so as not to fall into the trap of a one-target, one-compound solution mind-set.

The tapestry of synergistic nutrient and herbal benefits contained in food is woven from:

- Essential vitamins and minerals
- Fatty acids
- Fiber
- Thousands of phytochemicals including:
  - Terpenes
  - Polyphenols
  - Carotenoids
  - Isoflavones
  - Flavonoids
  - Chlorophylls
  - Alkaloids
  - Lignans
  - Phytosterols
  - Sulforaphanes
  - Stilbenes
  - Catechins
  - Tannins
- Folate
- Inositol
- Sulfides

Each food and nutrient, as well as bio-individual physical sufficiency of nutrients, either influences or is metabolized through detoxification pathways, including phase I CYP P450 isoenzymes, phase II conjugation enzymes, Nrf2 signaling,

and metallothionein [43]. CYP450 enzymes are essential for the production of cholesterol, steroids, prostacyclins, and thromboxane A_2. Within the population, there is genetic variability or polymorphisms of CYP450 enzymes, with about 50% of the population having normal function and the rest having altered rapid to very low function. So ultimately, we need to consider the patient's particular metabolism, often referred to as normal, rapid, or slow metabolizers, layered with the effect of nutrients, and then the effect of drug regimens. Viewed this way, it is an extremely complex undertaking [43].

Super doses or consumption of certain nutrients, either via food or food-based supplements, will influence specific enzymes in a dose-dependent manner. They may increase or decrease the function of a pathway or act as adaptogens, balancing the function of an enzyme. Consumption of bioactive supplements in this manner may or may not be therapeutic, while food forms are often better tolerated and less potentially problematic. A whole foods-intensive diet is the safest and most important way to optimize biofunction [44, 45].

26.9.4 Liquid Oral or Enteral Nutrition

A simple glance at the label of any commercial oral or enteral feeding product will explain why they should be avoided: Sugar, corn syrup, sodium caseinate, corn maltodextrin, soy protein isolate, corn oil, and canola oil form a who's-who list of what not to consume. These ingredients are generally genetically modified and contribute to the toxic burden of the body. Sugar and corn syrup are two of the preferred energy sources for cancer and contribute to obesity, one of the leading causes of cancer, as well as nonalcoholic fatty liver disease. Although high in calories, the only vaguely nutritive value is added synthetic vitamins. The added inflammatory and endocrine-disrupting potential of filler ingredients is in direct opposition to the needs of the cancer patient. There are far healthier products on the market made of real organic high-quality ingredients. The Oley Foundation is a fantastic resource for real food options for blenderized or tube feeding needs [46].

Batch cooking and preparation are extremely helpful since patients are generally exhausted during times that require the greater food absorption and digestive rest that liquid nutrition provides. True nourishing support can be found with the following: freshly made vegetable and fruit juice blends (low sugar), smoothies (made with low-sugar ingredients and greens), blended soups, protein powders (pea, hemp, grass-fed beef protein, grass-fed whey, nutritional yeast, egg white powder as tolerated), organic whole fruit and vegetable and grass powders, and bone broths and collagen support sourced from grass-fed, free-range, organic animals.

26.9.5 Tea Therapy

Tea is a simple, yet powerful, way to provide daily support for detoxification, reduction of inflammation, and overall cancer care. Tea is a gentle way to enter the herbal realm. As always, choose high-quality teas that are not contaminated with heavy metals, fluoride, or pesticides. Tea contains polyphenols that include the catechins, alkaloids (caffeine, theophylline, and theobromine), amino acids, chlorophyll, and minerals.

From the NIH National Cancer Institute [47], among their many biological activities, the predominant polyphenols in green tea—EGCG, EGC, ECG, and EC—and the theaflavins and thearubigins in black teas have antioxidant activity. These chemicals, especially EGCG and ECG, have substantial free radical scavenging activity and may protect cells from DNA damage caused by reactive oxygen species.

Tea polyphenols have also been shown to inhibit tumor cell proliferation and induce apoptosis in laboratory and animal studies [47]. In other laboratory and animal studies, tea catechins have been shown to inhibit angiogenesis and tumor cell invasiveness. In addition, tea polyphenols may protect against damage caused by ultraviolet (UV) B radiation, and they may modulate immune system function. Furthermore, green teas have been shown to activate detoxification enzymes, such as glutathione S-transferase and quinone reductase, that may help protect against tumor development. Although many of the potential beneficial effects of tea have been attributed to the strong antioxidant activity of tea polyphenols, the precise mechanism by which tea might help prevent cancer has not been established.

Chamomile tea is a potent source of apigenin [48]. Apigenins appear to play a role in gene regulation, essentially reprogramming cancer cells so they act more like normal cells and die on schedule. One of the most striking discoveries in this body of research is that apigenins could potentially stop the spread of breast cancer. The latest research suggests apigenin binds to one of three types of proteins, each with a specific function. One of those proteins is called hnRNPA2. In a healthy hnRNPA2 protein, only one type of splicing takes place [48].

However, in cancer cells, two types of splicing take place. This abnormal splicing is a factor in about 80% of all cancers. Splicing is important because it prompts the production of mRNA, or messenger RNA, which then carries out instructions regarding gene activation. When apigenin connects with the hnRNPA2 protein in breast cancer cells, it changes the protein from two splices back to a single-splice setup. And with splicing back to normal, cells are able to die on schedule—or, at the very least, they become more vulnerable to the effects of chemotherapy drugs [48].

Herbal tea blends are available to gently cleanse the liver, support the mucosal health of the digestive system, support throat and esophageal health, relieve nausea, and more.

26.9.6 Turmeric

Turmeric is a member of the ginger family, and the rhizome has been used for thousands of years for its healing properties. Although the active constituent, curcumin, is the focus of much research, there are a multitude of compounds

identified in the rhizome, and some research on curcumin-free turmeric indicates that these non-curcumin compounds, as well as the whole plant synergy, may hold equivalent efficacy [49].

Turmeric compounds include the yellow-colored polyphenols curcumin (diferuloylmethane), demethoxycurcumin (curcumin II), and bisdemethoxycurcumin (curcumin III), as well as turmerin, turmerone, elemene, furanodiene, curdione, bisacurone, cyclocurcumin, calebin A, and germacrone [49]. Studies have indicated that turmeric oil, present in turmeric, can enhance the bioavailability of curcumin. Dietary turmeric is especially important because consistent consumption in food overcomes some of the bioavailability issues of turmeric due to its hydrophobic nature, poor absorption, and metabolism. Different methods of delivery of curcumin have been studied, including using in combination with heat, fat, and the piperine compound from pepper. Much of these challenges are overcome naturally when turmeric is incorporated consistently in the diet [50]. Turmeric milk (turmeric mixed in warm milk) has been used for thousands of years as a tonic in India.

Evidence-based research indicates that turmeric possesses anti-inflammatory, hypoglycemic, antioxidant, wound-healing, antimicrobial, anticancer, and immune-supportive properties that support overall wellness [49, 50]. The polyphenol curcumin exhibits anticancer effects through a multitude of pathways, including the modulation of the cell cycle, by binding directly and indirectly to molecular targets including transcription factors (NF-kB, STAT3, β-catenin, and AP-1), growth factors (EGF, PDGF, and VEGF), enzymes (COX-2, iNOS, and MMPs), kinases (cyclin D1, CDKs, Akt, PKC, and AMPK), and inflammatory cytokines (TNF, MCP, IL-1, and IL-6).

There is upregulation of proapoptotic (Bax, Bad, and Bak) and downregulation of antiapoptotic proteins (Bcl(2) and Bcl-xL) [51]. Additionally, curcumin can suppress the activation of dendritic cells (DCs) by modulating the JAK/STAT/SOCS signaling pathway to restore immunologic balance in an experimental colitis model, colitis being a risk factor for colon cancer [52]. Because curcumin exhibits numerous mechanisms of cell death, it is possible that cells may not develop resistance [53].

Most critically of all, turmeric is proving to be an effective weapon against cancer stem cells in many types of cancer. Cancer stem cells (CSCs), as discussed above, are a subpopulation of tumor cells that possess the stem cell properties of self-renewal and differentiation. These cells have been identified in many solid tumors including breast, brain, lung, prostate, testis, ovary, colon, skin, and liver and also in acute myeloid leukemia. The CSC theory clarifies not only the issue of tumor initiation, development, metastasis, and relapse but also the ineffectiveness of conventional cancer therapies. Treatments directed against the bulk of the cancer cells may produce striking responses, but they are unlikely to result in long-term remissions if the rare CSCs are not targeted [54].

Curcumin was tested in a group of 25 advanced pancreatic cancer patients and found to induce tumor regression, induce tumor stability for 18 months, and reduce clinically relevant biomarkers, all without toxicity [55]. It was found to be safe for use in gemcitabine-resistant patients with pancreatic cancer [56]. Curcumin reduced the number and size of polyps found in the precancerous condition familial adenomatous polyposis (FAP). Curcumin reduces clinically relevant biomarkers in colorectal cancer that is refractory to chemotherapy. Pretreatment with curcumin considerably reduced the dose of cisplatin and radiation required to inhibit the growth of cisplatin-resistant ovarian cancer cells [57]. Curcumin combined with oxaliplatin may enhance efficacy of the latter in both p53wt and p53 mutant colorectal tumors [58].

Curcumin has been tested for safety and potential effect with the maximum tolerable dose range between 4 and 8 g per day. Bear in mind that combining curcumin with piperine will dramatically alter its bioavailability, thus changing that limit. All concurrent drug therapies should be checked for cytochrome isoenzyme activity to prevent toxicity and ensure efficacy [59].

26.9.7 Ginger

One of the ancient remedies for ailments ranging from stomach upset to aches and pains, the ginger rhizome now has a growing body of evidence of efficacy in cancer. There are many active compounds in this root, some of which are in the layer just under the peel, so when using the young root, it is best to scrub it, as opposed to peeling it, if making a tea, smoothie, or juice. If the root is harvested later, past the 9-month mark, the skin will be tougher and may need to be removed. The older roots yield higher amounts of ginger oil [60, 61].

The anticancer activity of ginger has many mechanisms including reducing inflammation, upregulating tumor-suppressor genes, cell-cycle arrest, inducing apoptosis via the mitochondrial pathway and production of ROS, inactivation of VEGF pathways, and modulation of signaling molecules such as NF-kB, STAT3, MAPK, PI3K, ERK1/2, Akt, TNF-α, COX-2, cyclin D1, cdk, MMP-9, survivin, cIAP-1, XIAP, Bcl-2, caspases, and other cell growth regulatory proteins [61] all essentially affecting a multitude of targets in the various stages of oncogenesis, angiogenesis, and metastasis. Additionally, ginger has been found to be neuroprotective, antiemetic, antimicrobial, antifungal, and protective of the liver, gastrointestinal system, and lungs [61, 62]. The main compounds of interest in ginger are terpenes, including zingiberene, β-bisabolene, α-farnesene, β-sesquiphellandrene, α-curcumene, zerumbone, and phenols including gingerol, paradol, and shogaol.

Ginger can be taken internally in the following forms: powdered spice, tea, pickled ginger, candied ginger, preserved ginger, ginger oil, or raw root, and it has been used in skin cancer research as a topical preparation. Ginger can stimulate appetite and enhance digestion. *Caution is advised* in patients on anticoagulants or with bleeding disorders [62].

Ginger has shown efficacy in the following cancers: skin, breast, lung, gastrointestinal, bile duct, pancreatic, ovarian, cervical, renal, prostate, liver, and brain. Ginger has been found helpful in ameliorating side effects of conventional treatment with radiation, doxorubicin, and cisplatin, as well as working synergistically with gemcitabine in pancreatic cancer by sensitizing tumor cells and suppressing tumor growth.

Interestingly, ginger combined with Gelam honey was found to produce more tumor cellular apoptosis than the use of 5-fluorouracil alone in the treatment of colorectal cancer cells [63]. The component zerumbone has been found to enhance the radiosensitivity of colon cancer cells. Beyond inducing apoptosis, autophagy, and modulating angiogenesis in ovarian cancer, ginger compounds may help to overcome chemotherapeutic drug resistance [64]. Perhaps the most encouraging research on ginger comes in the form of its ability to address stem and dendritic cells [65]. The ginger compound 6-shogaol was found to inhibit both breast cancer monolayer cells and stem cell spheroids at doses that are not toxic to normal cells [65, 66].

Also significant is the potential of 6-shogaol to decrease cancer development, progression, and metastasis by inhibiting the production of tumor-associated dendritic cells. The study reported tumor-associated dendritic cells (TADCs) facilitate lung and breast cancer metastasis in vitro and in vivo by secreting inflammatory mediator CC-chemokine ligand 2 (CCL2), but it is also the first to reveal that 6-shogaol can decrease cancer development and progression by inhibiting the production of TADC-derived CCL2. Human lung cancer A549 and breast cancer MDA-MB-231 cells increase TADCs to express high levels of CCL2, which increase cancer stem cell features, migration, and invasion, as well as immunosuppressive tumor-associated macrophage infiltration [66].

6-shogaol decreases cancer-induced upregulation of CCL2 in TADCs, preventing the enhancing effects of TADCs on tumorigenesis and metastatic properties in A549 and MDA-MB-231 cells. A549 and MDA-MB-231 cells enhance CCL2 expression by increasing the phosphorylation of signal transducer and activator of transcription 3 (STAT3), and the activation of STAT3 induced by A549 and MDA-MB-231 is completely inhibited by 6-shogaol. 6-shogaol also decreases the metastasis of lung and breast cancers in mice. 6-shogaol exerts significant anticancer effects on lung and breast cells in vitro and in vivo by targeting the CCL2 secreted by TADCs. Thus, 6-shogaol may have the potential of being an efficacious immunotherapeutic agent for cancers [66].

Ginger in all of its forms deserves a place of honor in our herbal healing arsenals for virtually all aspects of wellness, but specifically for cancer prevention and treatment.

26.9.8 Dandelion

Bitter greens, especially dandelion greens, are plentiful in the spring and have been used traditionally for centuries to stimulate bile and aid in phase 2 liver detoxification [67]. Dandelion flowers have antibacterial properties in their pollen; contain a terpene known as helenin, which is a powerful antifungal agent [68]; and are rich in vitamins A and B12. Dandelion leaves and flowers were found to be protective against UVB exposure and cellular senescence, suggesting potential use for UV sun protection and antiaging applications [69]. Perhaps the most powerful part of the dandelion is the root. The German Commission E has approved dandelion root for the treatment of disturbances in bile flow, stimulation of diuresis, loss of appetite, and dyspepsia.

The University of Windsor in Ontario is currently running the Dandelion Project, a clinical trial using dandelion root extract (DRE) for terminal cancer cases. Two refractory hematological malignancies experienced unusual responses to DRE [70]. DRE was shown to have the potential to induce apoptosis and autophagy in human pancreatic cancer cells with no significant effect on noncancerous cells [71].

Dandelion extracts have been used in traditional Native American medicine and traditional Chinese medicine to manage gastrointestinal and liver disorders. Upon study, DRE was found to be selectively cytotoxic to cultured leukemia cells [72].

Chronic myelomonocytic leukemia (CMML) is aggressive and highly resistant to treatment. DRE holds promise as a potential treatment [73]. DRE was shown to have selective efficacy in inducing two forms of programmed cell death in highly aggressive and resistant CMML cell lines. Rapid activation of caspase-8 not only activated the extrinsic pathway of apoptosis but also triggered pro-death autophagy selectively in these cells, suggesting that this extract has components that enhance its selective efficacy in targeting CMML cells. These results indicate that within the vast array of available natural products and compounds, there are nontoxic alternatives to conventional chemotherapy that are safe and effective [73].

And one of the most common cancers, colon, may also benefit from DRE treatment [74]. Phytochemical analyses of the extract showed complex multicomponent composition of the DRE, including some known bioactive phytochemicals such as α-amyrin, β-amyrin, lupeol, and taraxasterol. This suggested that this natural extract could engage and effectively target multiple vulnerabilities of cancer cells. Therefore, DRE could be a nontoxic and effective anticancer alternative, instrumental for reducing the occurrence of cancer cells drug resistance [74].

Dandelion root tea and extract are readily available and should be considered in all stages of treatment.

26.9.9 Methyl-Rich Foods

Methyl-rich foods are epigenetically powerful and include those that are high in folate, methionine, and choline, such as meat, fish, eggs, dairy, citrus, leafy greens, strawberries, and mushrooms [75].

Chemicals that enter our bodies can also affect the epigenome. One example, bisphenol A (BPA), is a compound

used to make polycarbonate plastic. It is in many consumer products, including water bottles and linings of tin cans. Controversial reports questioning the safety of BPA have prompted some manufacturers to stop using the chemical. In the laboratory, BPA appears to reduce methylation of the agouti gene in mice. Agouti mice studied show yellow mothers give birth to pups with a range of coat colors from yellow to brown. When mothers were fed BPA, their babies were more likely to be yellow and obese. However, when mothers were fed BPA along with methyl-rich foods, the offspring were more likely to be brown and healthy. The maternal nutrient supplementation had counteracted the negative effects of exposure [76].

From there, it is easy to see the cascade effect of how attention to methylation and epigenetic programming can mitigate daily exposure to toxins, thereby reducing cancer risk.

26.9.10 Melatonin-Rich Foods

We have previously discussed the critical role of melatonin on the immune system. The decline in the production of melatonin with age has been suggested as one of the major contributors to immunosenescence and the possible development of neoplastic diseases [77]. To further complicate matters, melatonin metabolism from dietary sources can compete in the liver with other compounds, can be impacted by hormones, is affected by cytochrome enzymes, and is subject to other clinical deficiencies, such as pyroluria [78]. Pyrrole disorder, sometimes referred to as the mauve factor, is consistently associated with higher incidence of mental health issues, such as ADHD, bipolar disorder, and schizophrenia, all of which can be mediated with vitamin and mineral therapy, thus impacting endogenous melatonin production. There can also be a focus on foods that contain the necessary B6 and zinc and cofactors such as folate, B12, and manganese [79]. Also, as with any phytochemical, plant levels are dependent on growing conditions and harvesting [80].

Some excellent dietary choices for melatonin are tart cherry juice, tart cherries, walnuts, mustard seed, tomatoes, chilies, almonds, pineapple, bananas, oranges, fenugreek seeds, sunflower seeds, corn, rice, ginger root, peanuts, grains, corn, asparagus, mint, black and green tea, broccoli, pomegranate, olives, Brussel sprouts, and cucumbers [81–84].

26.9.11 Honokiol

Honokiol is a phytochemical isolated from the bark and leaves of the magnolia tree [85]. Honokiol has been demonstrated to possess anticarcinogenic, anti-inflammatory, antioxidative, and antiangiogenic properties, as well as an inhibitory effect on malignant transformation of papillomas to carcinomas in vitro and in vivo animal models without any appreciable toxicity. Honokiol affects multiple signaling pathways in molecular and cellular targets, including nuclear factor-κB (NF-κB), STAT3, epidermal growth factor receptor (EGFR), cell survival signaling, cell cycle, cyclooxygenase, and other inflammatory mediators [85].

Honokiol can be used in combination with oxaliplatin in the chemotherapy of colon cancer. This combination allows a reduction in oxaliplatin dose, thereby reducing its adverse effects. It may also enhance the chemotherapeutic effect of oxaliplatin for this disease [86]. Honokiol inhibits migration of non-small cell lung cancer cells [87].

Molecular docking analysis of honokiol in EGFR binding site indicated that the chemotherapeutic effect of honokiol against head and neck squamous cell carcinoma (HNSCC) is mediated through its firm binding with EGFR, which is better than that of gefitinib, a commonly used drug for HNSCC treatment [88]. Furthermore, honokiol shows effectiveness against several multidrug-resistant tumor cells [89].

26.9.12 Limonene

Limonene is a bioactive monoterpene found in the peel of citrus fruit. Even though it was proven to completely regress mammary tumors in rats over 25 years ago [90], human clinical trials are lacking. However, a recent study on the metabolomics of limonene is very promising and suggests that limonene's activity is likely through a general systemic effect rather than through a specific target [91].

Limonene is distributed extensively to human breast tissue when eaten and results in reduced breast tumor cyclin D1 expression that may lead to cell-cycle arrest and reduced cell proliferation. Overexpression of cyclin D1 promotes the transition of cells out of the G1 and into the cell cycle and is commonly overexpressed and deregulated early in breast tumorigenesis in humans [92]. This is notable because cyclin D1 is a key regulator of cell proliferation. It also controls other aspects of the cell fate, such as cellular senescence, apoptosis, and tumorigenesis [93].

D-limonene enhanced the antitumor effect of docetaxel against prostate cancer cells without being toxic to normal prostate epithelial cells. This combined beneficial effect could be through the modulation of proteins involved in the mitochondrial pathway of apoptosis. D-limonene could be used as a potent nontoxic agent to improve the treatment outcome of hormone-refractory prostate cancer with docetaxel [94].

26.9.13 Cruciferous Vegetables

Broccoli, broccoli sprouts, cabbage, watercress, kale, and all cruciferous vegetables are high in isothiocyanates, such as sulforaphane, which have been found to not only prevent cancer but to reduce and slow the growth of existing tumors in bladder, breast, colorectal, endometrial, gastric, lung, ovarian, pancreatic, prostate, and renal cancers [95].

Sulforaphane induces apoptosis in human prostate cancer by initiating ROS generation [95]. Although sulforaphane garners much of the anticancer attention, there are other compounds working synergistically to power this potential, such as benzyl isothiocyanate (BITC). The three processes that are impacted by BITC are ROS production, autophagy, and apoptosis. When a cruciferous vegetable is chewed or macerated, the enzyme myrosinase is released from a cellular compartment to hydrolyze the glucosinolates, producing ITCs and other products. There are nearly 120 identified ITCs, with sulforaphane and BITC simply being very well studied [96].

The referenced studies explore direct anticancer properties, but there are other factors to be considered. Cabbage, for instance, contains a significant amount of the amino acid L-glutamine, as well as vitamins C and K, folate, B6, calcium, magnesium, manganese, selenium, chlorophyll, flavonoids, fiber, carotenoids, indole-3-carbinol, lignans, phytosterols, and sulfur bioactives (other than glucosinolates).

Glutamine is a rich component of cruciferous vegetables and is the most abundant amino acid in the body and conditionally essential, meaning that normally the body produces enough but can utilize much more under conditions of stress. Adding glutamine to parenteral nutrition prevents deterioration of gut permeability and preserves mucosal structure [97]. Glutamine has been shown to prevent muscle wasting, one of the confounding factors of cancer morbidity.

Adding glutamine to the nutrition of clinical patients, enterally or parenterally, may reduce morbidity. Several excellent clinical trials have been performed to prove efficacy and feasibility of the use of glutamine supplementation in parenteral and enteral nutrition. The increased intake of glutamine has resulted in lower septic morbidity in certain critically ill patient populations [98]. It has been found that the use of glutamine supplementation is safe and can diminish risks of high-dose chemotherapy and radiation. There is some evidence that adequate glutamine availability can beneficially affect outcome, especially in patients undergoing bone marrow transplantation [99].

Glutamine supplementation was found to protect against radiation-induced mucositis, anthracycline-induced cardiotoxicity, and paclitaxel-related myalgias/arthralgias. Glutamine may prevent neurotoxicity of paclitaxel, cisplatin, oxaliplatin, bortezomib, and lenalidomide and is beneficial in the reduction of the dose-limiting gastrointestinal toxic effects of irinotecan and 5-FU-induced mucositis and stomatitis. Dietary glutamine reduces the severity of the immunosuppressive effect induced by methotrexate and improves the immune status of rats recovering from chemotherapy. In patients with acute myeloid leukemia requiring parenteral nutrition, glycyl-glutamine supplementation could hasten neutrophil recovery after intensive myelosuppressive chemotherapy [100].

There are individual genetic influences to be considered that may affect the metabolism of isothiocyanates. The Linus Pauling Institute discusses this in detail [30, 101]. Once absorbed, glucosinolate-derived isothiocyanates (such as sulforaphane) are promptly conjugated to glutathione by a class of phase II detoxification enzymes known as glutathione *S*-transferases (GSTs). This mechanism is meant to increase the solubility of isothiocyanates, thereby promoting a rapid excretion in the urine. Isothiocyanates are thought to play a prominent role in the potential anticancer and cardiovascular benefits associated with cruciferous vegetable consumption. Genetic variations in the sequence of genes coding for GSTs may affect the activity of these enzymes. Such variations have been identified in humans. It has been proposed that a reduced GST activity in these individuals would slow the rate of excretion of isothiocyanates, thereby increasing tissue exposure to isothiocyanates after cruciferous vegetable consumption. GSTs are involved in "detoxifying" potentially harmful substances like carcinogens, suggesting that individuals with reduced GST activity might also be more susceptible to cancer [101].

Finally, induction of the expression and activity of GSTs and other phase II detoxification/antioxidant enzymes by isothiocyanates is an important defense mechanism against oxidative stress and damage associated with the development of diseases like cancer and cardiovascular disease. The ability of sulforaphane to reduce oxidative stress in different settings is linked to activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway. Some, but not all, observational studies have found that GST genotypes could influence the associations between isothiocyanate intake from cruciferous vegetables and risk of disease (see ▶ Chap. 17).

26.9.14 Seeds

Seeds such as sunflower, pumpkin, chia, hemp, flax, sacha inchi, and sesame are very rich in essential fatty acids, vitamin E, B vitamins, and minerals like selenium, phosphorus, iron, copper, zinc, and potassium. Some seeds contain a significant amount of protein. Hemp seeds in particular are a complete source of all 20 known amino acids and are 25% protein, higher than many other seeds, including chia and flax.

The benefits of lignans have been called into question for hormone-linked cancers due to their phytoestrogenic action. However, the Oncology Nutrition Practice Group of the Academy of Nutrition and Dietetics shares that lignans are the type of phytoestrogens in flaxseeds, and they may change estrogen metabolism [102]. In postmenopausal women, lignans may cause the body to produce less active forms of estrogen and is believed to potentially reduce breast cancer risk. There is evidence that adding ground flaxseeds into the diet decreases cell growth in breast tissue as well. Some cell and animal studies have shown that two specific phytoestrogens found in lignans, enterolactone and enterodiol, may help suppress breast tumor growth. Researchers do not yet know if these results will apply to women with breast cancer, but this approach—adding flaxseed to the diet—looks promising. And several studies in women have shown that higher intake of lignans, the key phytoestrogen in flaxseeds, is associated with reduced risk of breast cancer [102].

Further, lignans in the diet are associated with less aggressive tumor characteristics in women who have been diagnosed with breast cancer. In other words, women who have already been eating lignans at the time of diagnosis seem to have tumors that are less aggressive [102].

26.9.15 Medicinal Mushrooms

Mushrooms have been used medicinally since ancient times. The chief medicinal uses of mushrooms to date are antioxidant, antidiabetic, hypocholesterolemic, antitumor, anticancer, immunomodulatory, anti-allergic, nephroprotective, and antimicrobial [103]. The mushrooms known to have anticancer effects belong to the genus *Phellinus*, *Pleurotus*, *Agaricus*, *Ganoderma*, *Clitocybe*, *Antrodia*, *Trametes*, *Cordyceps*, *Xerocomus*, *Calvatia*, *Schizophyllum*, *Flammulina*, *Suillus*, *Inonotus*, *Inocybe*, *Funlia*, *Lactarius*, *Albatrellus*, *Russula*, and *Fomes*. The anticancer compounds play crucial roles as reactive oxygen species promoters, mitotic kinase inhibitors, antimitotic, angiogenesis inhibitors, and topoisomerase inhibitors, leading to apoptosis and eventually halting cancer proliferation [103].

A particular mushroom compound, Active Hexose Correlated Compound (AHCC), acts as a biological response modifier [104]. In vivo and human clinical trials have shown that AHCC modifies both the innate and adaptive immune responses by increasing the production of cytokines, increasing the activity of NK cells by as much as 300–800%, increasing populations of macrophages and in some cases doubling it, increasing the number of dendritic cells, and increasing the number of T cells by as much as 200%.

Data from the treatment of more than 100,000 individuals with various types of cancer have shown AHCC treatment to be of benefit in 60% of cases. AHCC is particularly effective for liver, lung, stomach, colon, breast, thyroid, ovarian, testicular, tongue, kidney, and pancreatic cancers [105]. In addition to being able to fight cancer directly, AHCC also alleviates many of the side effects of chemotherapy [106]. Chemotherapy is replete with side effects, which range from psychologically distressing to life-threatening. Doctors noticed that chemotherapy patients taking AHCC did not lose hair. Subsequently, an in vivo study found that mice treated with AHCC were protected from chemically induced hair loss. Clinical studies in Korea and Japan have indicated that AHCC remarkably improves symptoms of nausea and vomiting in cancer patients.

Chemotherapy inhibits bone marrow function, which can be life-threatening. AHCC has been shown to raise the white blood cell count of cancer patients by about 30% [106]. One of the major drawbacks of chemotherapy is the demise of healthy cells in addition to cancer cells. An in vivo study found that rats given chemotherapy without AHCC experienced large increases in liver enzymes while those given chemotherapy plus AHCC had normal levels of liver enzymes.

Importantly, in vitro and animal studies show that AHCC has anticancer effects, not just effects on chemotherapy side effects [107]. In cisplatin-treated mice, AHCC increased its antitumor activity while reducing side effects and showed synergistic effects with gemcitabine in pancreatic cancer cells. A prospective study showed early evidence that AHCC improves prognosis after curative resection of hepatocellular carcinoma. AHCC also reduced chemotherapy-associated adverse effects in patients with advanced cancer, and in those with pancreatic ductal adenocarcinoma [107].

26.9.16 Bee Products

Both integrative and conventional medicine support the use of bee products as elixirs for virtually every health condition, including cancer [108–110]. Propolis, honey, royal jelly, pollen, and even venom have been found to be antimicrobial, anti-inflammatory, antioxidant, immune supportive, antiparasitic (parasites are an often-overlooked initiator of cancer), antidepressant, capable of inducing apoptosis, helpful in increasing energy levels, and wound healing.

26.9.17 Iodine Sufficiency

Although all parts of the body contain iodine, many tissues and organs in our body concentrate iodine [111]. Organs that have a concentration function include thyroid, stomach mucosa, salivary glands, breast tissue, thymus, skin, placenta, ovaries, uterus, prostate, pancreas, choroid plexus, and the ciliary body of the eye. The role of iodine in these tissues is believed to include antioxidant, anti-inflammatory, antiproliferative, antibacterial, proapoptotic, and pro-differentiating effects [112].

Research suggests that the therapeutic form of iodine in breast cancer is molecular iodine (I_2) and that I_2 is capable of inducing apoptosis in human breast cancer cells through mitochondrial-mediated pathways [112, 113]. Iodine may also affect the binding of estrogen receptors, thereby having an antiestrogenic effect on gene expression. Gastric cancers, such as stomach cancer and Barrett's esophagus, were found to have decreased or absent iodine levels in gastric tissues [113]. The subject of iodine and companion minerals, such as selenium, for endocrine health and breast cancer prevention and treatment has been a topic of popular publications [114, 115]. Iodine-rich foods include seaweeds, sea vegetables, spirulina, and chlorella, with lesser amounts in cranberries, baked potatoes, pastured eggs, organic dairy, shrimp, wild caught fish, and navy beans [116, 117].

26.9.18 Seaweed and Algae

Spirulina and chlorella are nutrient-dense chlorophyll-rich blue-green algae [118–121]. Part of their benefit is that there is a significant amount of nutrition available in powder or tablet forms, which is perfect for when appetite is waning but nutrient needs are high. Rich in phytonutrients, B-complex

vitamins, carotenoids, iron, zinc, magnesium and other minerals, protein, amino acids, and fatty acids, they earn the rank of superfoods. Chlorella can increase excretion and decrease absorption of cadmium, lead, mercury, and other heavy metals, as well as radioactive particles [118–121].

Chlorella supports several aspects of immune function, including enhancing NK cell activity [122]. One preliminary study reported that patients taking chlorella suggested that the cellular components and functions of the immune system remained at near-normal levels and were less adversely affected when patients were undergoing chemotherapy and/or taking immunosuppressive medications such as steroids [122].

Fungal overgrowth is a common occurrence in oncology patients. The immunostimulatory effects of spirulina were reported to support clearance of systemic fungal conditions in a mouse model by increasing levels of tumor necrosis factor alpha and interferon gamma [123]. Phycocyanin, a component of spirulina, was found to induce apoptosis and autophagic cell death in pancreatic cancer cells [124]. One report indicates that the phycocyanin compound was able to affect multiple targets of oncogenesis in a variety of cancer types [125].

Seaweed is another nutritional powerhouse [126]. As with the algae, seaweed should be sourced carefully to obtain contamination-free products. Seaweed is a rich source of vitamins and minerals and is naturally high in iodine. Sea vegetables contain fucoidan, a polysaccharide studied for its ability to inhibit tumor development, induce cancer cell death, inhibit metastasis, protect against toxicity associated with chemotherapy and radiation, and act synergistically with certain chemotherapy regimens [126].

26.9.19 Fiber, Prebiotics, and Short-Chain Fatty Acids

A high-fiber diet decreases the risk of metabolic syndrome, thereby addressing one of the major risk factors for cancer [127]. The decreased transit time, dilution of fecal carcinogens, and increased microbial diversity of a high-fiber diet contribute to a decrease in cancer rates, including proximal and distal colon cancer [128], colorectal adenoma [129], breast cancer [130], and renal cell carcinoma [131].

The short-chain fatty acids (SCFAs), butyrate, propionate, and acetate, are generated in the large intestine through bacterial fermentation of dietary fiber and resistant starches [132–135]. Additionally, a rich source of butyrate can be found in bovine milk and milk-fat products such as butter and ghee. Insoluble fiber such as oat bran, wheat bran, and psyllium, as well as resistant starches found in cooked and cooled potatoes or rice, legumes, green bananas and plantains, or Jerusalem artichokes, supports the bacterial fermentation process. These foods act as prebiotics or nourishment for the healthy bacterial species that generate the SCFAs and serve to increase bacterial diversity, increase insulin sensitivity, reduce inflammation, and increase metabolism.

Butyrate has direct and specific anticancer potential [132–135], is known to induce autophagy and apoptosis of cancer cells, inhibits the growth of cancer cells in the bowel, supports the cancer-fighting effect of photodynamic therapy on astrocytoma cells, and increases the sensitivity of resistant cancer cells to irinotecan in the treatment of colon cancer. Propionate is mainly taken up by the liver and has been found to reduce systemic inflammation and counteract malignant cell proliferation in liver tissue [136].

26.9.20 Modified Citrus Pectin and Pectin

Modified citrus pectin (MCP) is a complex water-soluble indigestible polysaccharide obtained from the peel and pulp of citrus fruits and modified by means of high pH and temperature treatment. MCP has been found to sensitize prostate cancer cells to radiation therapy, overcome radioresistance, and reduce clinical radiation dose [137]. In addition, MCP has antimetastatic properties for multiple malignancies, including melanomas, and inhibits tumor angiogenesis and galectin-3, a regulator of cancer cell apoptosis which can increase the sensitivity of many cancer cell lines to various chemotherapies [138].

Pectin is a complex polysaccharide found in plant cell walls that acts as a natural gelling agent. When it interacts with acid, it produces compounds including arabinogalactans and galactans, which can bind to and inhibit galectin-3 as noted above. Pectin is also an excellent binding agent that may remove heavy metals such as mercury, lead, and aluminum, as well as radioactive particles from the body. It has been used in the Chernobyl region as recommended by the BELRAD Institute as part of food rations for children to effectively reduce the body burden of cesium [139].

MCP is protective against radiation-induced mucositis and works synergistically with doxorubicin to significantly increase the rate of apoptosis and limit the rate of cell-cycle division in prostate cancer cells [140]. MCP was also reported to be immune supportive and anti-inflammatory, protecting intestinal stem and epithelial cells against inflammation, especially following bacterial infection, by increasing tight-junction proteins and thus preserving the mucosal barrier [140].

Low-molecular-weight citrus pectin (LCP) effectively inhibits the growth and metastasis of gastrointestinal cancer cells, while demonstrating synergistic tumor-suppressor activity with 5-fluorouracil (5-FU) [141] against gastrointestinal cancer cells [142]. LCP can enhance the ability of oxaliplatin to inhibit cell proliferation and induce apoptosis, which may be associated with the activation of mitochondrial apoptosis pathways [143].

MCP affects numerous rate-limiting steps in cancer metastasis and works synergistically with chemotherapy and radiation treatment. It has been shown to be effective both in vitro and in vivo against prostate carcinoma, colon carcinoma, breast carcinoma, melanoma, multiple myeloma, and hemangiosarcoma. This is known as "one bullet with multiple targets" in oncology [144].

26.9.21 Fermented Foods and Probiotics

Fermented probiotic-rich foods and supplements support the health of the gastrointestinal system. The gut microbiome affects metabolism, nutrient absorption, and immune function. Certain strains can diminish the incidence of postoperative inflammation in cancer patients and relieve diarrhea resulting from radiation and chemotherapy. Some components of the immune response, including phagocytosis, natural killer cell activity, and mucosal immunoglobulin A production, can be improved by some probiotic bacteria [145]. *Saccharomyces boulardii* is an effective strain to prevent and resolve *Clostridium difficile* infection, antibiotic-associated diarrhea, and enteral nutrition-related diarrhea, all of which are concerns with immunocompromised oncology patients [146].

A review article on immunomodulation related to probiotics states the immune properties of the digestive mucosa are assisted by the gut-associated lymphoid tissue (GALT) [147]. The epithelial lining of the intestine comprises the primary physical barrier where immune responses are initiated. This intestinal barrier protects the host from the ingested external environment with a protective mucous layer, secretory IgA, and the tight junctions. Bacteria within the intestinal lumen interacts with intestinal epithelial and dendritic cells, macrophages, and lymphocytes. Probiotics modulate the immune system through the induction of cytokines from epithelial cells, and this is reported to be strain-specific [147].

There are high-quality nutraceutical probiotic blends tailored to specific needs that are strongly recommended for consideration for cancer prevention and during treatment. Good probiotic food choices include organic whole milk yogurt (if casein/animal milk is tolerated), organic kefir (if casein/animal milk is tolerated), fermented foods such as kimchi, sauerkraut, miso, and kombucha. If the patient is severely immunocompromised, each probiotic strain and food choice should be carefully researched to determine if it is appropriate for use.

26.9.22 Artemisia

Artemisia or wormwood plant contains powerful antiparasitic, antimicrobial, antifungal, and anti-inflammatory compounds, particularly artemisinin [148]. It is another multifaceted healer particularly in parasitic infections. Artemisinin has been found to reduce or prevent the formation of breast tumors [148], rapidly induce apoptosis in cancer cells [149], and recognized as an important worldwide medicinal plant [150, 151]. The entire plant, with all of its active compounds, is reported to be more effective than the artemisinin isolate [152]. Another study shows a synergistic cytotoxicity when artemisinin was used with butyric acid [153].

Lai and Singh have shown that with high concentration of iron in many types of cancer cells, it is possible to use this as a point of entry to induce selective apoptosis in leukemia cells by combining holotransferrin with Artemisia compounds [154]. This was also reported in radiation-resistant breast cancer cells [155], in drug-resistant small-cell-lung cancer cells [156], as well as a therapeutic effect against glioblastoma [157].

26.9.23 Carotenoid- and Polyphenol-Rich Foods

Carotenoids are red, orange, yellow, and green pigments found in plants and algae and include carotenes, xanthins, lutein, and lycopene. Partially functioning as antioxidants, certain carotenoids convert to vitamin A in the body, although that conversion is dependent on digestive function and absorption as well as thyroid function. Maceration or processing, cooking, and the presence of dietary fat increase the absorption of dietary carotenoids. Carotenoid-rich foods include carrots, sweet potatoes, peppers, dark leafy greens and lettuce, tomatoes, melons, cruciferous vegetables, squash, pumpkin, and citrus [158].

Polyphenols are responsible for the vibrant colors of fruit, berries, vegetables, and spices and add to their bitterness, astringency, flavor, and aroma. These phytochemicals are created by the plant in response to stimuli such as UV radiation, pathogens, bugs, and harsh climate [159]. In the human body, polyphenols help to reduce oxidative damage and inflammation, protect the skin from UV radiation, are neuroprotective, and help protect DNA from free radical damage and reverse epigenetic markers in the DNA, thereby preventing the development of cancer and reducing the growth of tumors.

The European Journal of Clinical Nutrition created a list of the 100 richest dietary sources of polyphenols. The richest sources were various spices and dried herbs, tea, some juices, whole grains, fruits, seeds and nuts, vegetables, cocoa products, and some darkly colored berries [160]. The bioavailability of polyphenols is increased when consumed with dietary fat.

Polyphenols found in pomegranate, green tea, broccoli, and turmeric have demonstrated significant anticancer effects involving angiogenesis, apoptosis, and proliferation, specifically in prostate cancer [161]. They can inhibit cancer cell growth by interacting with multiple signaling pathways in multiple cancers, including breast, gastrointestinal, prostate, pancreatic, lung, and ovarian, as well as refractory cancers and hormonally responsive cancers [162].

26.9.24 Essential Oils

Essential oils (EO) are aromatic volatile organic compounds that are the very olfactory essence of a plant [163]. They are typically extracted through steam distillation or cold-pressing. Their chemistry is extremely complex, consisting of

hundreds of unique chemical compounds or constituents that depend on everything from climate to the soil the plant is grown in to the sounds that the plant "hears" while growing. Drought will yield a plant that is higher in certain constituents that the plant expressed in order to survive those conditions. Ancient writings and traditions tell us that essential oils have been used for thousands of years and, alongside herbs, were perhaps man's first medicine, both for physical and spiritual purposes. Modern science seems to be on the cusp of uncovering the biochemistry of what has been used for millennia.

The last decade has brought scientific discoveries indicating that odor receptors are not found solely in the nose but throughout the body—in the liver, heart, kidneys, muscle tissue, skin, even sperm—where they are responsible for initiating important physiological functions [163]. When we inhale a fragrance, those molecules are recognized first by the chemical receptors that line the olfactory membranes in our nose. Olfactory receptors behave like a lock-and-key system, with an odor molecule the key to the receptor's lock. When the right molecule lines up with the right receptor, it sets in motion an elaborate choreography of biochemical reactions. These signals are transmitted to the limbic system and the olfactory sensory nerves at the base of the brain. From there, physiological functions can be initiated.

The constituents of EOs have been found to be antibacterial, antiviral, antifungal, anti-inflammatory, analgesic, antiemetic, anxiolytic, and antidepressive [164]. EOs and their constituents act by multiple pathways and mechanisms involving apoptosis, cell-cycle arrest, antimetastatic and antiangiogenic, increased levels of reactive oxygen and nitrogen species (ROS/RNS), and DNA repair modulation to show their antiproliferative activity in the cancer cell. Reports also discuss tumor-suppressor proteins (p53 and Akt), transcription factors (NF-κB and AP-1), MAPK pathway, and detoxification enzymes like SOD, catalase, glutathione peroxidase, and glutathione reductase [164].

The use of essential oils is making great strides in oncology as aromatherapy, massage oils, and primary treatment. This is supported by in vitro and in vivo clinical research [165, 166]. Be cautious as cold-pressed citrus oils can cause a photosensitive reaction [166]. Research also points to benefits associated with components of the Boswellia species, or frankincense. The positive outcomes have been attributed to boswellic acids, but this most recent case study of bladder cancer suggests that the hydrodistillates may also have significant effect [167].

EOs are analyzed and categorized via gas chromatography. They consist of the hydrocarbons, including the terpenes, such as pinene, beta-caryophyllene, myrcene, limonene, chamazulene, and farnesene, and the oxygenated compounds, which are mainly esters, aldehydes, ketones, alcohols, phenols, and oxides. Each plant's essential oil contains a unique profile of a combination of these constituents, and thus its own particular biochemical potential application.

26.10 Dietary Interventions

Dietary interventions for cancer treatment are abundant, but common sense should be the ruling factor. Low-carbohydrate, vegetable-fruit phytonutrient-rich and nutrient-dense whole foods are fundamentals for all oncology dietary recommendations. Certain diets may be very beneficial for a period of time for detoxification or healing but may not be supportive for the long term. Think of it in the same terms that you would with conventional treatment: acute and maintenance interventions. Tailored targeted care should be prescribed depending on the patient's current treatment. Remain flexible and responsive to the whole person, and avoid being locked into a doctrine or belief that does not serve the patient's needs.

26.10.1 Seasonal Eating and Living

Humans are creatures of light and dark seasons and respond best when caring for themselves within the parameters of their location on the earth, with a nod to their heritage and genetics. For instance, in Ayurveda, seasonally balanced eating based on the seasons and a person's individual balance of dosha is essential: bitter greens in the spring to cleanse and detoxify the liver, gallbladder, and pancreas; cooling fruit and citrus in the summer to balance heat-induced lethargy; root vegetables, nuts, fats, meat, and hibernation foods in the autumn to conserve energy; and tonics in the winter to support the kidney, bladder, and heart in the darker months of contemplation and rest (see ▶ Chap. 45). Despite modern-day conveniences and artificial light and stimulation, at our core, we are disrupted when we do not remain in sync with nature. Simply contemplate the effect of blue light at night on our endocrine health or the stress of technology on our emotional health (see ▶ Chap. 34). Harmony with our natural surroundings and striving to balance what is lacking in our environment if we are city dwellers, should be our goal. This theory is applicable at all times for all people.

26.10.2 Autoimmune Paleo Diet

This approach is an effective strategy for reducing inflammation and promoting gut healing. The AIP diet removes most potentially inflammatory and typically allergic foods and focuses on nutrient-dense foods: vegetables, limited fruit, proteins including organ meats, fermented foods, and bone broths. However, in an oncology setting, it is important to not be overly focused on proteins as too much protein stimulates the mTOR pathway and contributes to the growth of cancer [168].

The mammalian target of rapamycin (mTOR) is an ancient molecular-signaling pathway that, when inhibited, will upregulate maintenance and repair, increase longevity, and impede the growth of cancer. When stimulated, it will allocate nutrients for growth, replication, and reproduction.

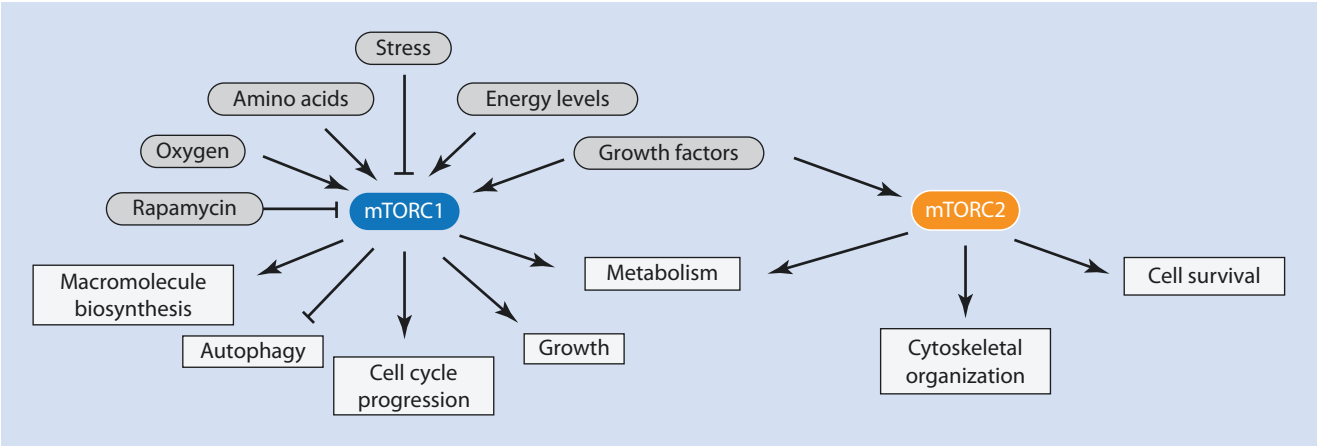

Fig. 26.2 mTOR: master regulator of the nutrient-sensing hormones insulin, leptin, and insulin-like growth factor (IGF). (Adapted from Laplante and Sabatini [168]. With permission from Elsevier)

The human biological imperative is geared toward reproduction to keep the species alive, as opposed to longevity. mTOR is a master regulator of the nutrient-sensing hormones insulin, leptin, and insulin-like growth factor (IGF), determining where and how nutrition will be used. Reducing protein intake reduces IGF, which in turn increases life span [169]. Glucose and amino acids are nutrients and fuel necessary for replication and reproduction. If glucose, amino acids, insulin, and growth factors like IGF are kept low, mTOR is suppressed, thereby allowing the upregulation of the genetic expression of maintenance and repair. mTOR also plays an important role in autophagy. A similar process is known as mitophagy, where damaged mitochondria are removed and replaced with new, healthy ones, and this process is also largely regulated by mTOR (Fig. 26.2).

There is new evidence that protein restriction may be even more important than the restriction of net carbohydrates [170]. This theory has in fact been tested and found to hold true. One study reported that longevity and health were optimized when protein was replaced with carbohydrate. The authors reported that longevity may be extended in ad libitum-fed animals by manipulating the ratio of macronutrients to inhibit mTOR activation [170]. However, the conservation of protein may be even more important than the manipulation of carbohydrates. There is general agreement in oncology that the ideal amount of protein daily should not exceed 1 g per kilogram of lean body mass [171].

26.10.3 Vegetarian Diet

A vegetarian diet is a nourishing option as long as it involves consuming primarily vegetables and fruit, with a healthy dose of healthy fats. Unfortunately, many times, a vegetarian diet focuses on refined starches, like pasta, and other foods devoid of nutritive value that impart no healthful benefits, verging on a junk food diet at its most extreme. When a vegetarian diet consists of organic vegetables and fruit with enough healthy fats to ensure the absorption of the phytochemicals, it provides enough protein to satisfy biological requirements and, with attention to bio-individual needs, can be essentially autoimmune in nature [172]. Vegetarianism is really a spectrum of diets that is based on eating only plant-based foods but may include certain food groups such as dairy, eggs, and fish or may avoid cooked foods, as in the raw diet.

26.10.4 Ketogenic Diet

The research around the ketogenic diet and cellular metabolism is compelling (see ▶ Chap. 22). An ideal ketogenic diet is rich in healthy fats (70%), sufficient in clean proteins (25%), and low in carbohydrates (5%). This typically induces a state of nutritional ketosis where the body burns fat as fuel instead of sugar-glucose-carbohydrates, generating fewer reactive oxygen species (ROS) and secondary antioxidants, thereby lowering inflammation [173]. The effect of a ketogenic diet on the mitochondrial energy metabolism of cells may indicate that an additional hallmark of altered metabolism should be added as a hallmark of cancer as described by Ward and Thompson in 2012 as altering cell signaling and blocking cellular differentiation. Altered metabolism is a direct response to growth factor signaling [174]. Most cancer cells and proliferating normal cells still derive a significant fraction of their ATP through oxidative phosphorylation. Oxidative phosphorylation is the foundation of energy production within the ketogenic diet [174].

» Data now support the concepts that altered metabolism results from active reprogramming by altered oncogenes and tumor suppressors and that metabolic adaptations can be clonally selected during tumorigenesis. Altered metabolism should now be considered a core hallmark of cancer [174].

In normal cellular metabolism, cells convert glucose or glycogen stored in the liver into pyruvate through glycolysis. In an aerobic environment, this will result in the production of ATP

via the Krebs citric acid cycle (CAC) or tricarboxylic acid cycle (TCA) through the electron transport chain, known as oxidative mitochondrial phosphorylation. Normal cells are able to adapt to utilize glutamine and ketones for energy production in a reduced glucose or fasting environment.

In the early twentieth century, German biochemist Otto Warburg noted that cancer cells produced lactate as a by-product, essentially a fermentation process in which the focus is on proliferation as opposed to energy production. Cancer cells are found to behave this way whether in an aerobic or anaerobic environment. Warburg believed this was due to damaged mitochondria [175]. The Warburg effect is the basis behind the PET scan, which delineates potentially cancerous areas based on uptake of a glucose-based tracer. Altered metabolism stems from damaged mitochondria, results from reprogramming of signaling pathways to sustain proliferation, and evades growth suppression and/or cell death [174].

Revisiting this consideration of mitochondrial cellular metabolism provides for a different potential application of diet in oncology. Restricting glucose to induce ketosis can theoretically optimize mitochondrial function, therefore directly impacting the malignancy and transformation of cells. In contrast to the nuclear somatic mutation, research across a broad range of tumor types, animal species, and experimental techniques has shown that normal mitochondria can suppress tumorigenicity. Nuclear transfer experiments suggest that tumorigenesis arises more from mitochondrial defects than from somatic mutations in the nuclear genome [176].

Ketogenic diets may act as an adjuvant cancer therapy by increasing the oxidative stress inside cancer cells and may also potentiate radiation and chemotherapies. A small trial of 10 patients with advanced cancer found that a ketogenic diet was able to halt or regress disease based on the extent of ketosis [177].

The combination of a ketogenic diet with hyperbaric oxygen therapy (HBOT) was found to have a synergistic effect and to inhibit tumor progression and prolong survival in animal studies [178]. A paleo-ketogenic diet alone has been shown to halt the progression of and partially regress a soft palate tumor in a patient over a 20-month period [179]. In many ways, a ketogenic diet mimics the effects of calorie restriction, such as reducing inflammation, decreasing side effects of treatment, potentiating standard therapies, and reducing cachexia [180].

26.10.4.1 Bio-individual Diets and Protocols

A bio-individual protocol entails assessing all aspects of the patient's condition, as discussed within this section, and then crafting a program of diet, supplements, detoxification, exercise, and emotional support that will address both their terrain and cancer. Some colon cancer patients have had colitis their whole lives, while others have been chronically constipated. Some lung cancer patients were heavy smokers, others never smoked. Some patients have deep emotional considerations to account for, others are well adjusted. Each of these nuances needs to be accounted for and addressed. It's really a marriage of ancient medicine with today's science.

Many clinics and physicians around the country are embracing these integrative strategies with successful outcomes, including case studies of work originally from Dr. William Kelley and subsequently from Drs. Nicholas Gonzalez and Linda Isaacs. Their approach is based on the pancreatic proteolytic enzyme research of the Scottish embryologist John Beard, who worked at the University of Edinburgh at the turn of the twentieth century [181].

This is an excellent summation of this concept, taken from an interview done by Dr. Conners with Dr. Gonzalez [182]:

» We divide patients into different metabolic categories, depending on each patient's particular genetic, biochemical and physiological make-up. In this model, patients with solid epithelial tumors, such as tumors of the lung, pancreas, colon, prostate, uterus, etc. do best on a largely plant-based diet. Such patients have a metabolism that functions most efficiently with a specific combination of nutrients that are found in fruits, vegetables, nuts, whole grains and seeds, and with minimal to no animal protein.

On the other hand, patients with the blood or immune-based malignancies such as leukemia, myeloma and lymphoma do best on a high-animal protein, high-fat diet. Such patients do extremely well with a diet based on animal products with minimal to moderate amounts of plant-based foods, the particular design of the diet again depending on the individual patient's metabolic make-up. We find patients with pancreatic cancer always do best with a largely plant-based diet that emphasizes fruits, vegetables and vegetable juice, nuts, seeds and whole grains. Allowed protein includes fish one to two times a week, one to two eggs daily and yogurt daily, but no other animal protein. In our therapy, we use diets specifically because of the effect of food on the autonomic nervous system. This system consists of the sympathetic and parasympathetic branches and ultimately controls all aspects of our physiology, including immune function, cardiovascular activity, endocrine function and the entire action of our digestive system. The sympathetic and parasympathetic systems have opposing actions on the target organs and so can adjust our physiology depending on needs and demands, enabling our bodies to react to any situation, condition or stress. We believe disease, whatever the form, occurs because there is an imbalance in autonomic function. For example, we find solid tumors, such as tumors of the breast, lung, pancreas, colon, uterus, ovaries and liver, occur only in patients who have an overly strong sympathetic

nervous system and a correspondingly weak, ineffective parasympathetic nervous system. We believe that blood-based cancers, such as leukemia, lymphoma and multiple myeloma, only occur in patients that have an overly developed parasympathetic nervous system, and a correspondingly weak sympathetic nervous system. Previous research, such as Dr. Francis Pottenger's research during the 1920s and 1930s proposed that much if not all disease has autonomic imbalance as at least one of the major causes.

We have found that specific nutrients and foods have specific, precise and predictable effects on the autonomic nervous system. For example, a vegetarian diet emphasizes fresh fruits and vegetables, particularly leafy greens, and contains large doses of minerals such as magnesium and potassium. It has been shown in many studies that magnesium suppresses sympathetic function, while potassium stimulates parasympathetic activity. Furthermore, a largely vegetarian diet tends to be very alkalinizing, and the neurophysiologic research documents that in an alkalinizing environment, sympathetic activity is reduced, and parasympathetic activity increased. So, whatever other effect a vegetarian diet has, in terms of autonomic nervous system function, such a diet will reduce sympathetic activity and stimulate the parasympathetic system.

A meat diet is loaded with minerals such as phosphorus and zinc, which tend to have the opposite effect. A high-meat diet stimulates the sympathetic system and tones down parasympathetic activity. Furthermore, such a diet is loaded with sulfates and phosphates that in the body are quickly converted into free acid that in turn stimulates the sympathetic nervous system while suppressing parasympathetic activity.

So, by the careful use of diet, we are able to effect major changes in autonomic function and bring about balance in a dysfunctional nervous system. We find, further, as the autonomic system comes into greater harmony and balance, when the autonomic branches are equally strong, all systems – from the immune system to the cardiovascular system – work better regardless of the underlying problem. In essence, we are using diet to bring about greater physiological efficiency. For cancer patients, long experience has taught us that it is not enough to load patients with enzymes; the question of autonomic imbalance must also be addressed. In terms of pancreatic patients specifically, a plant-based diet provides all the nutrients to correct autonomic dysfunction. –Dr. Nicholas Gonzalez

Essentially, no one diet is perfect for everyone or all conditions; there are just far too many factors to take into consideration. But the prevailing concept of eating clean whole foods in moderation will always be sensible. Conquering the challenge of cancer and enabling healing are being accomplished on a field full of players who have opened their minds to the newer science of cancer as a metabolic disease rather than genetic in order to remain focused on the patient and every potential avenue to serve that patient on their cancer journey.

26.11 Integrative Therapies Adjunctive to Nutrition Therapy

26.11.1 Hyperthermia

Hyperthermia has been used with an intent to cure tumors for at least 4000 years and as a tool for the destruction of tumor masses well before that [183]. Hyperthermia effectively stimulates metabolic activity, triggering the release of stored toxins through detoxification pathways. Hyperthermia helps your body to mimic a fever response, which is what it uses normally to fight infection and cancer. Therapies include whole-body hyperthermia, hyperthermic intraperitoneal chemotherapy, radio-frequency ablation, regional hyperthermia, and the most recent advance, laser interstitial thermal therapy. Laser interstitial thermal therapy (LITT) is an emerging technique being used to treat primary and metastatic brain tumors by implanting a laser catheter into the tumor and heating it to temperatures high enough to kill the tumor [184]. Hyperthermia or infrared therapy can extend to patients' homes. Excellent options exist to provide support on a daily basis and for the long term, such as home infrared heating pad devices or an in-home infrared sauna.

26.11.2 Mindfulness Practices or Meditation

Mindfulness meditation is defined as the nonjudgmental awareness of experiences in the present moment [185]. The components through which mindfulness meditation exerts its effects are regulation of attention, body awareness, self-awareness, and regulation of emotion.

Emotions hold the power to manifest wellness or illness. Ancient practices of medicine tell us that improperly processed emotions create stagnation and block energy meridians in our body. Because humans are electrical beings, these blocked channels can result in physical illness. The hormonal stress response to prolonged stress, anger, hopelessness, fear, and chronic fatigue can contribute to immune suppression. Learning to live life as a meditation from moment to moment is one of the keys to a peaceful life.
